| Function             | Adaptive significance of a trait, i.e., how it leads to increased fitness.                                                                                                                                                               |
| Mating effort        | Effort allocated to mate attraction and/or exclusion of sexual competitors. Separate from parental effort.                                                                                                                               |
| Mechanism            | Machinery enabling behaviors to be expressed, particularly neuroendocrine systems.                                                                                                                                                       |
| Ontogeny             | Development of an individual over its lifetime (conception to death).                                                                                                                                                                    |
| Parental behavior    | Behavior that originated and/or is currently being maintained to enhance offspring fitness. Costs to parents not considered.                                                                                                             |
| Parental care        | Any parental trait (behavioral or non-behavioral) that enhances offspring fitness. Costs to parents not considered. The trait may have originally evolved to serve functions other than increasing offspring fitness.                    |
| Parental effect      | Casual effects that a parent’s phenotype has on an offspring’s phenotype over and above direct genetic effects (i.e., an environmental source of variation). Called maternal or paternal effects (female or male parents, respectively). |
| Parental effort      | Combined fitness costs (sum of parental investment) incurred by parents due to the production and care of offspring produced in a given period. Separate to mating effort and incorrectly synonymized with parental expenditure.         |
| Parental expenditure | Usage of parental resources (energy, time, mass) on parental investment. Incorrectly synonymized with parental effort. Calculated as a proportion of the parent’s total resource budget allocated to investment.                         |

|           |                                                                                |
|-----------|--------------------------------------------------------------------------------|
| Proximate | Ontogeny of a trait or mechanisms that result in the expression of that trait. |
| Ultimate  | Evolution of a trait or function of that trait.                                |

## Definition

Any behavioral and/or physiological contribution by a parent in an offspring that increases the survival/fitness of that offspring at a cost to the parent's ability to invest in other offspring (Trivers 1972).

## Introduction

Sexually reproducing animals invest in offspring metabolically through the generation of gametes (eggs and sperm). Beyond this initial energetic investment, the majority of animals provide no additional investment in their offspring. However, in species that do provide parental investment following conception, the quantity, quality, form, and duration of investment vary dramatically between species, as well as between the sexes within species (Clutton-Brock 1991). In vertebrates, females often show a disproportionately higher metabolic level of investment than males through the generation of yolk or placenta that provides nourishment for the developing embryo (Clutton-Brock 1991; Trivers 1972).

Confusion over what constitutes “parental investment” has occurred due to the use of diffuse terminology (see Glossary of Terms), the inclusion or exclusion of particular behaviors at the discretion of different authors, and difficulties associated with assessing the relative costs and benefits to both offspring and parents (Alonso-Alvarez and Velando 2012). Furthermore, confusion has arisen because of the variety of approaches adopted to understanding parental investment. Nikolaas Tinbergen (1907–1988), a Dutch biologist who studied the behavior of animals in their natural environment, suggested that behavior could be studied from four aspects, namely, the proximate (i.e., ontogeny and mechanisms) and ultimate (i.e., function and evolution). While parental investment

has been extensively studied, studies tend to focus on only one of Tinbergen's (1963) approaches. For example, Trainor and Marler (2002) focused on the mechanisms associated with paternal care in California mice *Peromyscus californicus*, while Gubernick and Teferi (2000) focused on the function of paternal care. Consequently, there is a need to integrate these approaches to afford a unitary understanding of parental investment.

## Behaviors Associated with Parental Investment

A physiological contribution to investment can often be directly measured (e.g., quantity of yolk supplied to an egg). However, the categorization of behavior is more difficult because behaviors may serve multiple functions. For example, a bird may build a nest for shelter for itself, but the nest may also house offspring at a later stage. Thus, nest building could be viewed either as having no influence on offspring fitness or having a direct influence. For a behavior to be considered investment, the survival of offspring must be increased in response to the performance of the behavior, and the parent must suffer a cost that reduces its ability to invest in other offspring (Trivers 1972).

Behaviors can be classified as either indirect or direct (Table 1). Indirect behaviors are performed while away from the young (i.e., no physical contact) but still influence offspring survival, growth, and/or development (Fedy and Martin 2009). In contrast, direct behaviors are performed in the presence of the young and directly influence offspring survival, growth, and/or development (Gubernick and Teferi 2000). Both types of behaviors can vary between and within taxa (Table 1), and their roles in offspring development and fitness can vary over time.

Behaviors can also be categorized based on the timing of occurrence, occurring either pre- or post-birth/hatching (Table 1). Several indirect behaviors typically occur before egg deposition or birthing of young. Generally, a suitable site must be selected (Fetherston et al. 1990). Following site selection, nest/den/burrow-building

**Parental Investment, Table 1** Categories and types of parental investment and timing of occurrence. Example species and their associated behaviors are provided, along with key references

| Category                           | Type            | Timing of occurrence         | Example species                                           | Example behaviors                                                                                                                                                | Key reference                 |

species then construct the “home” in which offspring grow and develop (Coe 1974). The site, inclusive of the “home,” must then be maintained by removing pathogens, parasites, and fungi (Mennerat et al. 2009), and parents must also defend the site from conspecifics that would usurp the parents (Sato 1994).

For egg-laying species, following egg deposition, parents continue to defend the eggs from predators and conspecifics and also continue to maintain the eggs, removing dead or diseased eggs, parasites, pathogens, and fungi to maintain egg health (Skolbekken and Utne-Palm 2001; Table 1). Some animals forgo nest construction, rather transporting eggs in (e.g., gastric-brooding frogs *Rheobatrachus silus*) or on (e.g., pipid frogs *Pipa carvalhoi*) their bodies (Trueb and Cannatella 1986). Birds and some reptiles incubate the eggs, providing an appropriate thermal environment to ensure proper embryonic growth and development (Fedy and Martin 2009). For

birds, in particular, males can expend considerable energy in provisioning the female and protecting the eggs during the incubation period (Požayová et al. 2009). In contrast to egg-laying animals, most female mammals provide direct investment through internal gestation, which provides all the nutrition and protection the embryo needs (Gittleman and Thompson 1988).

Other behaviors are performed following the hatching/birthing of young (Table 1). Typically, parents protect offspring from conspecifics, predators, and kleptoparasites (Požayová et al. 2009). Territory maintenance can also be critical for ensuring offsprings gain access to high-quality resources or are protected from predation (Runcie 2000). Parents also continue to maintain the site (as for pre-hatching/birthing). Parents with dependent young spend considerable amounts of time provisioning young, either through lactation, regurgitation, or the presentation of food items (Malcolm and Marten 1982).

In some species (e.g., canids), males may also continue to provision females following the birthing/hatching of young. Huddling to provide warmth is especially important in mammals and birds, particularly when young are unable to thermoregulate at birth (e.g., rodents; Gubernick and Teferi 2000). Other direct post-birth behaviors include cleaning (grooming and licking, which can also be important to stimulate evacuation of waste), retrieval of young that have strayed from the nest/burrow (Gubernick and Teferi 2000), and carrying or transportation of young (Schradin and Anzenberger 2001). For social animals, additional behaviors that occur following birth include sentinel behavior and alarm calling to alert young of approaching predators (Runcie 2000), babysitting, and socializing, which can include play (Sharpe 2005).

**Costs Associated with Investing in Offspring**

Parents spend energy, time, and body mass on investment (i.e., parental expenditure).

Consequently, the ability to invest in offspring is often not shared equally among parents and is also dependent on various factors, including, but not limited to, environmental hazards and mating opportunities (Woodroffe and Vincent 1994). The main costs of parental investment manifest as a reduction in fecundity, decreased parental survival (Clutton-Brock 1991), and a reduction in future mating opportunities (Woodroffe and Vincent 1994). Therefore, because behaviors associated with self-maintenance (e.g., foraging/feeding, mating, avoiding predators) and parental effort are functionally discrete (i.e., behaviors are mutually exclusive), parents must trade off between these behaviors using cost-benefit strategies (Fig. 1; Alonso-Alvarez and Velando 2012).

**Trade-Offs Between Foraging and Investment**

Animals require energy to grow, develop, repair tissues, and maintain behaviors. Therefore, animals must invest time and energy in foraging (Fig. 1a). Energy acquired from foraging can be diverted directly to the parent for its maintenance, increasing its survival and fitness (Fig. 1a). Alternatively, the energy can be diverted to other behaviors,

**Parental Investment, Fig. 1** Costs (C) and benefits (B) of engaging in different mutually exclusive behaviors. Trade-offs indicated by double lines with cost-benefit

relationships explained in each of the four corners (assuming animal engages in a particular behavior). Individual points explained in the text

namely, predator avoidance, parental investment, or mate-seeking (Fig. 1b, c, d). Energy diverted to parental investment can increase offspring survival, growth, and development but at a direct cost to the parent, and this cost only increases as the number of offspring in a clutch/litter increases (Fig. 1a). Gestation, lactation, egg incubation, and food provisioning are energetically expensive and time-consuming (Gittleman and Thompson 1988) and can lead to a reduction in parental body condition. For example, two-spotted goby *Gobiusculus flavescens* males guard and fan eggs until the fry hatch, showing a reduction in feeding behavior as eggs age, resulting in decreased male body condition (Skolbekken and Utne-Palm 2001). As offspring grow, they place increasing demands on parents for nutrients and resources. Parents must either increase their food intake to meet these growing demands, which can increase their likelihood of predation (Fig. 1a), or must accept this loss in body condition, which can further lead to increased susceptibility to diseases, parasites, and pathogens as they become immunocompromised (Alonso-Alvarez and Velando 2012). This trade-off between parental investment and parental self-maintenance, however, can still lead to an increase in parental fitness through increased offspring survival.

### Trade-Offs Between Predation Risk and Investment

Adults are exposed to increased predation risk during foraging and mate-seeking. However, the presence of offspring can also attract predators, increasing the risk of predation to both adults and young (Fig. 1b). Predation risk can be increased by the physical activity of the young (e.g., begging calls) and increases as clutch or litter size increases (Fig. 1b). The activity of parents also provides sensory cues to predators, increasing the likelihood that young may be predated. These factors lead parents to trade off between caring for fewer, current offspring against caring for more offspring in the future (Alonso-Alvarez and Velando 2012). This trade-off is also impacted by other factors (Fig. 1b), including the quality of the external environment (e.g., high resource availability = reduced time needed for foraging = reduced predation risk to parent = greater

investment in young = reduced predation risk to young), the mating/social system of the species (e.g., social species = more eyes to spot predators = reduced predation risk to young), and the experience of the parents (e.g., more experience = better quality investment = reduced predation risk to young).

### Trade-Offs Between Mate-Seeking and Investment

Animals expend time and energy finding a suitable mating partner (mating effort; Fig. 1d). For species that engage in physical competition, the costs (e.g., energy required for fighting and investment in testosterone, loss of body condition, injury, or death) can be significant. These costs may be offset by foraging, where energy is diverted to mate-seeking (Fig. 1d), or by the production of offspring, where energy is diverted to parental investment (Fig. 1c). However, because mate-seeking and investing in offspring are mutually exclusive, adults must trade off between investing energy in young or securing additional matings (Fig. 1d; Alonso-Alvarez and Velando 2012). In mammals, males are not constrained to invest in young before their birth. Therefore, the opportunity for males to desert females is high (Woodroffe and Vincent 1994). However, multiple matings can also incur significant costs, such as increased predation risk (Fig. 1d). Furthermore, when environmental conditions are harsh and unpredictable, resource limitation may constrain adults to invest in offspring to ensure offspring survival (Rymer and Pillay 2018), even if this comes at a significant cost due to lost body condition of adults. However, by trading off parental effort against mating effort under stressful conditions, parents may ultimately benefit via increased offspring survival (Fig. 1c).

### Understanding Parental Investment from Tinbergen's Perspective

Distinguishing between Tinbergen's (1963) proximate questions is challenging because of the complex interactions between ontogeny and the mechanisms driving the expression of behavior.

While the brain and central nervous system (i.e., the behavioral machinery) are critical for allowing behaviors to be expressed, ontogenetic factors can modify this machinery, leading to behavioral changes (Rymer and Pillay 2018).

### Proximate Questions: Ontogeny and Mechanisms

The neuronal complexes involving the medial preoptic area, bed nucleus of the stria terminalis, amygdala, vomeronasal organ, accessory olfactory bulb, lateral preoptic area, substantia innominate, and ventral tegmental area provide the behavioral machinery responsible for the expression of parent-typical behaviors (Rymer and Pillay 2018). This neural network is laid down by organizational hormonal effects (permanent, nonreversible changes in neural substrates) during early development (pre-, peri-, or early post-natal) and is activated later during adulthood by activational hormonal effects (nonpermanent, reversible changes due to modification of neural activity; Schradin and Anzenberger 1999). The neuroendocrinological regulation of parental investment thus begins early in development and is likely to be homologous between the sexes because it is easier to construct a single neural complex (in an evolutionary and functional sense) than evolve different neuroendocrine circuits for males and females (Rymer and Pillay 2018).

However, sex-specific patterns of gonadotropin secretion, principally testosterone and estradiol, during ontogeny affect the neuroendocrine circuitry differently, leading to sex-specific differences in parental investment in adulthood, although these responses are likely to be species-specific (Rymer and Pillay 2018). For example, in prairie voles *Microtus ochrogaster*, overexposure to testosterone while females are still in the womb leads to a reduction in parental responsiveness as adults (Lonstein and De Vries 2000). The male testes begin steroid production while the offspring are still in the womb, whereas the female ovaries remain inactive during this period. This leads to differential exposure of neonatal male and female

brains to testosterone and estrogen, which may ultimately influence sex differences in parental responsiveness during adulthood (Lonstein and De Vries 2000).

As individuals grow and develop, testosterone and estrogen continue to influence patterns of parental investment, particularly in paternal males, where paternal behavior is promoted through aromatization of peripheral testosterone into estradiol in the medial preoptic area (Trainor and Marler 2002). However, other hormones, particularly vasopressin, oxytocin, and prolactin, may also influence the expression of parental investment. Vasopressin, which may be stimulated by testosterone via activity of estradiol, and oxytocin are structurally similar neuropeptide hormones that are secreted by the posterior pituitary into the general circulation, and both are associated with parental investment. Both oxytocin and vasopressin can mediate the release of prolactin, which is a gonadotropic hormone that can cross the blood-brain barrier exerting a direct influence in the brain and affecting the central control of parental investment (Schradin and Anzenberger 1999). Circulating prolactin is correlated with parental investment in fish, birds, and mammals (Schradin and Anzenberger 1999), suggesting that the underlying neural circuitry governing its regulation is organized early in development but activated later in life. Social stimuli and cues from offspring (particularly tactile cues) have been suggested to influence prolactin secretion, although other factors (e.g., environmental factors) may also play a role (Schradin and Anzenberger 1999). Finally, other hormones, including cortisol, dopamine, progesterone, and serotonin, also influence parental investment through their influence on prolactin and vasopressin secretion.

Parental investment is not wholly an innate property of endocrine-specific events. In particular, components of parental investment may be heritable (e.g., maternal care in African striped mice *Rhabdomys pumilio*, Rymer and Pillay 2011a). Parental investment is also mediated by genetic mechanisms, where several candidate

genes/loci associated with the expression of vasopressin, oxytocin, serotonin, estrogens, glucocorticoids, dopamine, prolactin, and progesterone influence parental behaviors, including nursing in rats *Rattus norvegicus*, maternal infanticide in pigs *Sus scrofa*, and paternal retrieval in house mice *Mus musculus* (Champagne and Curley 2012). Parental investment may also have an epigenetic component. For example, variation in parental behavior (e.g., licking/grooming and arched-back nursing) during the early post-natal period can cause long-term changes in neuroendocrine function in offspring, with parental investment of these offspring being altered, as a consequence, in adulthood (Champagne and Curley 2012). These effects could be driven by changes in neural structure or regulation of the hypothalamic-pituitary-adrenocortical (HPA) axis or could occur via DNA methylation or histone acetylation (Champagne and Curley 2012).

The development of parental investment is also influenced by the exposure of individuals to conspecifics. Indirect genetic effects (IGEs) occur when the genotype of an individual affects the phenotype of a conspecific via environmental influences (Wolf et al. 1998). Maternal and paternal effects are specific IGEs that occur when the parents are influenced by environmental factors (e.g., pesticides or resource availability), which then impacts the development of offspring/grand-offspring, or when the investment of one parent is influenced by the behavior of the other parent or by the offspring themselves (Wolf et al. 1998). For example, the absence of the father leads to increased maternal care (compensation) in African striped mice females, resulting in sons raised by mothers alone providing more care to their offspring as adults (Rymer and Pillay 2011b). Consequently, the ontogeny of parental investment could result from a net effect of the interactions between proximate and social factors.

### Ultimate Questions: Function and Evolution

The primary benefit of parental investment to parents is increased offspring survival because this increases parental fitness (Clutton-Brock

1991). Investment affords protection from the external environment and supports development and growth in multiple ways (Table 1). Variable or unpredictable environments may result in increased predation risk, food shortages, pathogens, and desiccation, which could negatively impact offspring survival and growth. However, these negative environmental factors may be mediated or buffered by the parents. For example, foam-nest frogs *Chiromantis petersi* build a foam nest with a hard exterior over small seasonal pools (or even animal mud wallows; Coe 1974). The nest protects from desiccation and predation until the tadpoles are ready to be released to the pond below, and tadpole release can be delayed if the weather remains dry for some time (Coe 1974).

Some aspects of investment are essential for offspring survival (obligate). For example, the deposition of energy and nutrients into eggs is essential for growth and survival at the time of hatching in egg-laying species (Clutton-Brock 1991). However, other aspects of investment may be expressed only conditionally (facultative). For example, while male burying beetles *Nicrophorus orbicollis* usually provide paternal care for a short time after eggs hatch, females can raise young alone, and brood mass may decrease if males remain with the brood for an extended period (Fetherston et al. 1990). While facultative investment may not be essential for survival, it may provide other benefits to parents and offspring, such as improved reproductive competitiveness of offspring later in life.

The fitness consequences associated with parental investment will determine if it will spread in a population (i.e., natural selection). Parental investment is thus expected to evolve when the benefits of investing in offspring outweigh the costs (Klug et al. 2012). Kin selection theory (i.e., Hamilton's rule) may be suitable for explaining the evolution of parental investment because of the close genetic relationship shared by parents and offspring, as any selection on offspring impacts selection on parents and vice versa (Kölliker et al. 2010). Parental investment should, therefore, evolve in situations where the indirect/

inclusive fitness of the parent/s is increased by investing in the current brood/litter. However, including inclusive fitness benefits is problematic because attempting to assign indirect fitness benefits across generations confounds selection effects (e.g., increased offspring survival as a consequence of investment received) with inheritance effects (e.g., inheritance of traits that increase survival until recruitment). Furthermore, the evolution of parental investment is likely linked with other forms of social behavior (e.g., mate attraction, competition, and group-living, suggesting that investment is also likely under antagonistic selection (Kölliker et al. 2010). That is, selection favors offspring receiving investment because this can increase growth and survival, but there is also selection against parental investment because the costs can be very high (Kölliker et al. 2010).

Parental investment evolved independently in different lineages. However, the evolution of investment within lineages is debated, and patterns of parental investment are likely specific to species and life-history strategies (Klug et al. 2012). Parental investment may evolve when individuals have a reduced capacity to reproduce in future breeding attempts, resulting in increased investment in the current litter/brood. This is likely a consequence of ecological (e.g., food availability) and social (e.g., population density) factors. In harsh environments, where resource competition may be intense, parents may be constrained in their investment of current young to ensure their survival (Klug et al. 2012). However, the environment cannot solely explain the evolutionary origins of investment, and numerous hypotheses (e.g., paternity certainty, mating effort, and physiological constraints) can all explain the evolution of parental investment in different taxa (Rymer and Pillay 2018).

The social environment may also have been important for the evolution of investment because behavioral interactions can shape the development of phenotypes. Parents transfer numerous non-genomic resources (e.g., proteins and hormones) to offspring that may be essential for development, and these parental effects may

result in phenotypic accommodation (adaptive adjustment of the phenotype, without genetic change, following a novel genetic or environmental stimulus occurring during development, West-Eberhard 2005). This variation underlying phenotypic accommodation could ultimately be shaped by selection (genetic accommodation) if it had an underlying heritable component (West-Eberhard 2005), leading to the establishment of parental investment. In addition, other behaviors used in different contexts (e.g., aggression toward conspecifics) could have provided a starting point from which parental investment could be modified (e.g., aggression co-opted into guarding of offspring). Once investment originated, co-evolutionary feedback loops may have led to the maintenance, further evolution, or even diversification of parental investment traits (Klug et al. 2012).

## Conclusion

Parental investment is widespread in the animal kingdom and varies between taxa, within taxa, and between the sexes. Parental investment is costly. The benefits associated with increased offspring survival and fitness are traded off against these costs. Trade-offs occur between self-maintenance, foraging, mate-seeking, and antipredator behaviors. Parental investment can be studied from any one of Tinbergen's (1963) four approaches. However, a complete understanding of parental investment requires that all four aspects be integrated.

### Synonyms

Parental care; Parental investment; Rearing

### Definition

Parenting is the investment by caregivers in their offsprings' survival to the age of reproductive viability, and to assure that the offspring possess the social skills necessary to compete for resources and reproduce. According to Trivers, the quality and length of the investment is shaped by a series of tradeoffs between the caregivers' needs to invest in additional offspring and each individual offspring's desire to optimize their own survival by exploiting their parents' resources. Parental goals include raising reproductively - viable offspring to adulthood, with minimal cost to their own reproductive capability. Offspring goals include obtaining as much care from their parent(s) as possible. These goals are, at times, in conflict, but at the root of successful parenting behavior lies the task of increasing offspring probability of survival to an age at which they are independent from their parent for survival, possessing the behavioral skills to attract a mate and successfully reproduce.

### Introduction

From an evolutionary perspective, one of the defining characteristics of a mammal, particularly females, is that they engage in parenting. While all mammals provide milk to their newborn offspring, parenting involves far more than the provision of calories and nutrition through lactation. As newborns, most mammals are relatively helpless, or altricial. They need protection from predators and, in the case of most non-ungulate mammals, they also require external warmth to

thermoregulate, both of which are typically provided by mothers. Even ungulates, who are capable of adult-like locomotion within hours of birth, require the protection of a parent as they respond to their native curiosity and explore their surroundings.

### Offspring-Caregiver Conflict

A primary feature of mammalian infants is an inherent curiosity (Harlow 1958), which drives them to learn about their environment, oftentimes leading to offspring-caregiver conflict. Young infants are driven to discover their environment and, in social species, to find agemates that will assist in their critical learning through play. Caregivers, on the other hand, tend to focus on keeping their offspring in close proximity to prevent injury or predation, an evolutionary-driven goal, as infancy is the period when the greatest loss of life occurs in most species. These diverging goals lead to conflict between the parent and the offspring (Trivers 1974). Indeed in rhesus macaques (*Macaca mulatta*), it is not unusual to see a mother grasping her curious infant's tail in a leash-like fashion to prevent it from leaving her side to explore. Parents must attend to and, at times, intervene to prevent their infants' incursion into novel and sometimes dangerous situations, while offspring recklessly seek out novel experiences and playmates, inherently trusting that their caregiver will keep them safe from harm and danger.

With increasing offspring age, this conflict reverses. As offspring develop the motor maturity and skills to fend for themselves, they become increasingly capable of independence from their parent, which is a primary parental goal. In line with this, as offspring age, their caregiver provides a decreasing amount of "hands-on" care and begins seeking new reproductive opportunities to invest in new offspring. Offspring, on the other hand, continue to seek resources from their parent(s) and tend to become distressed when their parent(s) focus on future reproductive opportunities.

As their mother becomes focused on mating and future offspring, and as offspring maintain their interest in their own needs and the resources a parent provides, weaning becomes a central feature

of offspring-caregiver conflict (see section “[Parental Investment Theory](#)” below). For example, while most Old World primate species are allowed continuous access to their mother’s nipple during the first weeks of life, as the infant ages and is more likely to survive without this care, and as the mothers’ continued investment in lactating leads to her missing out on reproductive opportunities, maternal carrying of and nursing infants are gradually reduced (Hinde and Atkinson 1970). The infant however, tends to continue to seek out nourishment and to have its psychological needs met by its mother. Thus, the weaning period can be a stressful period of time for both parties, as mothers reject their infant’s attempts to nurse and, consequently, infants become distressed and increase their attempts to maintain contact (Berman et al. 1993), with individual differences in both the parent and infant in the relative ease or difficulty of weaning. During the breeding season (the period when weaning is at its peak (Hinde and Spencer-Booth 1967)), of nonhuman primates such as rhesus monkeys it is not unusual to hear a cacophony of infant cries from the trees while their mothers engage in consort relationships (personal observations of author JDH from both the Morgan Island and Cayo Santiago free-ranging populations). Among some nonhuman primate species, the distressed infant may be comforted by siblings or fathers (e.g., tamarins (*Saguinius*) (Cleveland and Snowdon 1984), barbary macaques (*Macaca sylvanus*) (Deag 1980), and gorilla (*Gorilla*) species (Smuts et al. 1986)), and in some New World species, the father may increase his role significantly, acting as the primary caregiver (see section “[Fathering](#)” below).

## Parental Investment Theory

For caregivers, cost of reproduction is high, particularly for species whose young require care for an extended period of time following birth. As caregivers are typically limited in the amount of time and resources they can devote to any one offspring, parents must make decisions that will maximize the likelihood of offspring survival to sexual maturity, and therefore, the likelihood of extending the parents’ initial genetic contributions

to future generations, while balancing their own interest in reproducing again and investing in future offspring. Parental investment theory, proposed by Robert Trivers (1972), suggests that as parental investment into offspring involves expenditure of energy by the parent (i.e., time spent rearing offspring, energy spent carrying and protecting offspring, energy spent producing milk, etc.), each investment reduces the parent’s own reproductive fitness (i.e., possibilities of conceiving more offspring). While parents make a series of decisions about how much they will invest in the present offspring this must be balanced by potential investment in and the offspring themselves grapple for as much parental investment as possible, securing their own survival to an age of reproductive viability. Thus, parental investment is shaped by the demands of the offspring and the goals of the parent and must be optimized to meet the needs of both. While some species have opted for a higher birth rate, providing minimal parenting to their offspring beyond stashing eggs in a secure location (i.e., turtles, fish, frogs) (termed *r*-selection), others have opted for *K*-selection, having a lower birth rate and expending a substantial amount of time and energy rearing, feeding, and protecting their young (i.e., elephants, cats, primates) (MacArthur 1962), with the manifestation of *r*-vs.-*K*-selection not always clear. For example, among humans in societies where infant mortality is high and a lower percentage of the population live to a reproductive age, families tend to be larger than in modern or western societies where infant mortality is low and the vast majority live to reproductive age. It is clear that the type and quality of parenting invested into offspring is a reflection of our evolutionary history, and the current environmental demands, and that the cost of parenting is carefully assessed to promote reproductive success, and, therefore, the survival of the species.

## Parenting and Brain Development

A large brain requires a long time to grow. Consequently, growth must occur post-parturition. If not, mothers would likely die giving birth to large-

headed offspring as the birth canal is not equipped for such stress. Thus, a large brain arrives into the world underdeveloped, and appropriate input must be available for the brain to attain species-typical maturity. This phenomenon requires mammalian parents to devote more time and energy to parenting than do cold-blooded species, and primates take this to the extreme, with the vast majority of development of higher level brain functioning occurring postnatally. Even across primate taxa, there is wide-variation in infant needs, for example, infants of Old World primate species (i.e., chimpanzees (*Pan*), orangutans (*Pongo*), macaques (*Macaca*)) tend to have longer developmental periods of infancy in which they require maternal care, when compared to New World (i.e., marmosets (*Callitrichidae*), squirrel monkeys (*Saimirinae*), owl monkeys (*Aotus*)) or prosimian species (i.e., lemurs (*Lemuroidea*), lorises (*Lorisoidea*), aye-aye (*Chiromyiformes*)). This prolonged altricial period of Old World species is likely an evolutionary adaptation to their more complex adult brains, the complexity of social groups, and the requisite behaviors necessary for social living (Allman and Martin 1999), and a tendency toward a longer inter-birth intervals, and thus, a longer maternal investment.). With their long process of learning and development, primates possess certain features that set them apart from other mammals, including long lifespans (Charnov and Berrigan 1993) and bigger brains in relation to body size (Allman and Martin 1999).

From an evolutionary perspective, these features appear to be interrelated to the extent that altricial offspring require longer periods of post-natal development, in which a larger and more complex brain develops, allowing more rapid adaptation to changing and varied environments later in life. Furthermore, species with a longer lifespan and greater intelligence typically show comparatively more multifaceted behaviors and are capable of living in large societies that provide defense from predators and greater safety to developing infants. Such societies are typically organized around infant survival and are, in many ways, a macrocosm of the offspring-caregiver relationship, with males responsible

for troop defense and mothers bonding with other females to support one another. In this protective social setting, parents provide the input in which the immature infant's brain learns how to adapt to a vast number of circumstances, social challenges, learning to solve difficult social problems.

Infants, are born with a specific set of needs and expected inputs that must be met for normative neurodevelopment to occur, a concept called the experience-expectant brain in the developmental literature. Sensitive and attentive caregivers provide infants with the expected experiences, assuring that the right input is received by the under-developed brain at the right time. This parental input "wires" up the brain to develop to survive in its present environment, with the consequence of an immature brain requiring an oftentimes extensive period of investment to ensure survival to adulthood. *K*-selected species opt for a larger and longer parental investment to ensure their offspring's safety and physical health, as well as prepare them for a life as an adult member of the species. For example, observations of a mother cat (*Felis*) and her kittens indicate that, initially the mother produces energy-rich milk for her offspring, which declines in quality with time, and when her offspring are more mature, the mother teaches them to hunt to obtain their own food. In particular, for species living in complex social groups, parents provide critical opportunities for offspring to practice social skills, wiring up the brain to survive in a complex, social world. An underdeveloped brain at birth also provides for parenting that is calibrated to individual differences in offspring needs and to differences in environmental requirements, promoting the adaptability and survivability of the species as a whole.

To develop normally, infants must achieve an optimal level of arousal. That a parent reduces infant arousal via parenting behaviors is central to the development of mother-infant attachment bonds (arousal regulation theory) is grounded in the Yerkes-Dodson Law, proposed in the early 1900s by Robert Yerkes and John Dodson. The law posits that an optimal level of arousal is preferred for optimal performance. For an extensive

discussion on this theory and its relation to development, see ► [“Attachment”](#) entry.

Briefly, while adults are mature enough to regulate their own arousal, altricial infants' brains are not equipped to do so due to their immature emotional neural circuitry. The brains of species in which natural selection has favored a prolonged process of post-natal brain development form and maintain synapses if they are useful and prune them when they are not ecologically necessary. Through the formation of attachment bonds, adequate experiences occur and expected inputs are received, largely by repeatedly “turning off” the anxiety circuit in the brain as the caregiver nurtures and cradles their infant. By responding to the infant's over-arousal, the caregiver modifies their own behavior, with a goal of maintaining the infant's arousal at the optimal level. Optimal arousal is most readily achieved when a caregiver sensitively responds to their infant's needs, with individualized care. Similarly, when an infant is under-aroused, a caregiver will allow them to explore and play, with a goal of increasing arousal to the optimal level. By so doing, the caregiver sensitively engages the immature neural pathways in an experience-expectant manner until the infant matures to point that it can adequately regulate its own arousal.

## Transmission of Culture

A prolonged period of development with close parental oversight allows for the occurrence of the intergenerational transmission of extensive information concerning how to exploit the environment and solve problems. Observational learning of skills unique to a species, or specific to an ecological niche, or that provide insight into how to solve a problem that better adapts an immature individual to exploit a resource is an asset that provides an advantage to the developing offspring as it learns the skills that adults use. Outside of humans, direct tutoring and active teaching is rare, but the passive transmission of information (termed cultural transmission) via observation occurs frequently in the animal world and is one of the fundamental aspects of parenting in

primates as well as other species with long developmental periods (e.g., elephants, dolphins, whales) and is likely one of the major reasons for primates' success, as each generation gains access to knowledge honed and refined by earlier generations.

One salient example of this transmission of culture is that of the chimpanzee termite-fishing. Chimpanzees are a particularly-altricial species, relying on their mothers until they are between 8 and 10 years of age (Goodall 1967), closely observing their mothers to learn the skills they need to exploit their environment. Termite fishing is one such skill. Chimpanzee offspring observe their mothers insert a stick into a termite mound and extract termites to eat. As offspring are typically clumsy when they first begin applying this skill, chimpanzee mothers give them ample opportunities to observe and practice, and tend to be tolerant of their offspring's behavior, even when it disrupts the termite-fishing bout (Lonsdorf 2006).

Another example of this intergenerational transmission of culture is the washing of sweet potatoes by Japanese macaques (*Macaca fuscata*) found on Koshima Island. In 1953, one female was observed washing a sweet potato before consuming it. Over the next decade, this behavior spread through the troop. Over the next decade, all but four of the infants born into the troop learned the behavior from their parents. Such transmission of knowledge from parent to offspring is a fundamental parental function that has great benefit to species with long developmental periods (Hirata et al. 2001).

## Alloparenting and the Kin Selection Hypothesis

In some species, members of the social group beside the mother provide care for related offspring, in a process called alloparenting or aunting (Wilson 1975). Alloparenting is most clearly expressed in primates (Hrdy 1976), though it is seen in some other mammals, like porpoises and elephants, as well as in some insects and birds. A few hypotheses propose explanations as to why

**Parenting, Table 1** This table shows the proportion of genetic-relatedness between individuals in a family. Darker colors (and higher percentages) indicate greater genetic-relatedness

|               | Offspring | Mother/Father | Sibling | Step-sibling | Aunt/Uncle |

alloparenting occurs. One of these states that, for nulliparous (no experience as a biological mother) females, alloparenting provides an opportunity to practice motherhood and gain experience caring for an infant (Lancaster 1971).

While this learning-to-mother hypothesis has been cited by many, there are clear drawbacks to this vein of thinking. For instance, what about males that participate in alloparenting? They are clearly not learning to mother. The kin-selection hypothesis accounts for this, suggesting that, as the primary goal of parenting is to promote the survival of one’s own offspring to an age of reproductive viability, parental investment is based on getting one’s own genes into the next generation. Fathers that care for their offspring increase the probability of their sons’ and daughters’ survival; thus getting their genes into the next generation. As mothers care for their offspring they are investing primarily in an individual that is 50% genetically related to them (her offspring – see Table 1) rather than an individual that is 100% genetically related to her (herself – see Table 1). If she were to only invest in herself, she may well ensure that she has enough resources for survival but as she will one day die, if she has no offspring, her genes will cease to appear in the next generation, assuming she has no siblings and therefore no nieces or nephews. It is proposed that in species which alloparent, those providing the care are investing in offspring that are their genetic relatives. For example, as a male sibling cares for their infant sibling, they are investing in an individual that is 50% genetically - related to them (see Table 1). As an aunt or an uncle cares for their infant niece or nephew, they are

investing an individual that is 25% genetically - related to them (see Table 1).

Therefore, as an individual cares for an infant that is related to them by some degree, they are ensuring their own genetic survival into the next generation.

**Parenting Styles**

Among most mammals, mothers are the primary, if not the sole caregiver, with males showing disinterest and, in some cases, engaging in infanticide (see Hrdy 1977), particularly when the infants are not sired by him. For rhesus monkeys, mothers play a primary role in parenting and infant development. This is thought to be because, when compared to males, females make a greater investment in the developing fetus and infant. Beginning with her investment of an ovum at conception, to her body’s dedication to house the developing fetus, to her investment in feeding and caring for the infant, the energetic costs are substantial, and much greater than that of the father. Put another way, sperm is cheap; ova are costly, and while males can produce multiple offspring in a year with little cost, females, particularly most primate females, are only able to produce approximately one infant in a year. That mothers are the main caregiver in most Old World species is largely a function of that initial investment. The intensive care that altricial infants require following birth necessitates that parenting play a crucial role in the survival of primate offspring to an age of reproductive viability. While primate parents invest differentially in their infants across species, parenting quality has been demonstrated to have

lasting effects on infant outcomes, including survival, social skills (Pereira and Altmann 1985), and normative development (Harlow 1958).

Because mothers are the primary caregiver in most species, their skillfulness, temperament, and style of care matters. While all mammalian females show certain similarities, largely centered around feeding, there are wide individual differences in the quality of care and maternal restrictiveness. For example, studies of the maternal behaviors of monkeys reared without mothers demonstrate that, for female primates, the complexities of maternal behavior are not merely a set of hardwired fixed-action patterns, but rather something that must be learned (Seay et al. 1964). Studies have investigated the role of mothering styles on development, suggesting that sensitive parenting (i.e., attentive, calibrated to the infant's individual needs) is linked to healthy, normative brain development, whereas less involved or insensitive parenting (i.e., permissive, abusive, restrictive) is linked to abnormal brain development (Maestripieri et al. 2006).

Early maternal experiences may also explain the evolutionarily-old phenomenon of offspring abuse in human and nonhuman primates as mothering styles are believed to be transmitted intergenerationally. For example, Widom and colleagues show that maternal child abuse in humans is often transmitted from one generation to the next (2015) in a process called the intergenerational transmission of abuse. In nonhuman primates, Fairbanks and McGuire (1988) identified two general maternal traits, protectiveness and rejection. Protectiveness is behaviorally - characterized by frequent maternal approach, making contact, restraint, and infant inspection. Rejection is behaviorally - characterized by high rates of rejection, breaking contact, and maternal leaving her infant. Such treatment tends to be stable and studies show the female infants mirror their mothers' parenting style when they care for their own infants. For example, Maestripieri (2005) identified rhesus monkey mothers with a history of abusive parenting and rhesus monkey mothers with no history of abusive care (control group). When the abusive monkey mothers and the control mothers gave birth, their

infants were cross-fostered to one another (i.e., the abusive mothers adopted the offspring of the control mothers and the control mothers adopted the offspring of the abusive mothers). As expected, the abusive mothers abused their cross-fostered infants and the control mothers did not. When the abused and the non-abused infants became adults and had their own offspring, the researchers observed that the mothers that were abused as infants were more likely to abuse their own infants, while none of the non-abused, cross-fostered mothers abused their own infants, despite their genetic-relatedness to an abusive mother. Other studies of nonhuman primate abuse suggest that propensity of mothers to engage in offspring abuse is tempered or exacerbated by genetic background (McCormack et al. 2009).

Beyond abusive parenting, studies investigating the role of maternal presence on offspring development derive from Harry Harlow (see ► [“Attachment”](#) entry). In these paradigms, infants are removed from their biological mothers at birth and raised with a warm, cloth-covered surrogate mother or a wire surrogate mother to which they can cling and from which they can feed (Harlow 1958). The results of these studies show that certain inherent maternal features make a mother a desirable maternal figure to the infant (see ► [“Attachment”](#) entry). For example, the cloth-covered surrogates provide warmth, softness similar to a mother's touch, and are universally preferred by the infants, which seek comfort from the surrogates in times of distress through clinging to the soft surrogate “bodies.” These studies suggest that, at least for primates, infants need more than milk, and that mothers are preprogrammed to fill those needs.

## Fathering

While mothers tend to be the primary caregiver of most nonhuman primate species, fathers play a role in parenting to varying degrees (see Mitchell 1969 for a review). For most Old World species, mothers are the primary caregiver and fathers play, at best, a limited role (Snowdon and Suomi 1982). For example, in the classic 21-month field

study of rhesus macaques, Lindberg (1971) only observed 66 incidents (less than 2 minutes total time) of an adult male carrying an infant. Some have suggested, however, that this may be a function of the restrictiveness of the mother that generally does not allow a male to approach her infant, but instead quickly retrieves her infant when a male approaches (Lindberg 1971). Two studies assessed adult males' interest in and psychological capacity to care for infants when the mother was not present. In both studies, the adult male carried and performed all the behaviors characteristic of the mothers, except nursing (Redican and Mitchell 1973; Gibber and Goy 1985). Remarkably, when the females were returned to the groups, mothers quickly retrieved their infants and the males ceased to exhibit infant care, suggesting that the male rhesus monkeys are capable of caring for an infant, but do not engage in infant care due to maternal restrictiveness, likely a product of evolution. However, in monogamous species, such as gibbons (*Simiiformes*) and siamangs (*Simiiformes*), some prosimian species, as well a variety of New World species, biparental caregiving is more readily observed and, in the case of *Callitrichidae*, fathers and siblings play a primary role in infant care (Cleveland and Snowdon 1984).

Across most Old World species and in many New World species that live in large social groups, males are more likely than females to take a role in the infant's macroenvironment, protecting and defending the infant as a member of the larger troop against outsiders and predators. Adult males do, however, tend to engage in play more often with infants and juveniles than do adult females (Brockelman et al. 1998), something that the infants and juveniles seem to enjoy, as they often elicit these interactions. Adult males will also break up a fracas when juveniles and adolescents become overly-rowdy. Fathers tend to play an indirect role in their offspring's overall survival. For example, in species that show limited paternal caregiving, when the father of a male offspring remains in the troop, the rhesus macaque son grows faster and is less likely to be injured (Huchard et al. 2013), and in yellow baboons, both male and female offspring tend to mature to

an age of reproductive viability more quickly (Charpentier et al. 2008) when their father is present.

Not all fathers in Old World species are uninvolved in their infants' lives. For example, the barbary macaque spends considerable time interacting with infants, with infant play, infant carrying, and infant grooming all central features of barbary macaque society (Deag and Crook 1971). Similarly, in species, where the male is more likely to be certain that they are the sire or in species that live in harems (e.g., *Hamadryas* baboons (*Papio hamadryas*), gorillas), males are not only tolerant of their offspring but will even engage their offspring in co-sleeping.

While males in New World species that live in large groups exhibit behaviors toward infants that parallel the behaviors of Old World species, monogamous *Callitrichidae* species show a great deal of paternal care, with the male often acting as the primary caregiver (Mitchell 1969). This unusual pattern of male-infant care is explained as a unique adaptation to the species-typical twinning behavior (i.e., bearing two infants at once), where the energetic cost of carrying and feeding the infant precludes a female from caring for her twins by herself. To put this in perspective, two infant marmosets weigh as much as 25–30% of the mother's total body weight. If this were to occur in a human, a mother weighing 54 kg would be carrying twins weighing about 14 kg, an enormous energetic cost that would hinder her ability to both feed and carry the twin infants. Thus, for a female marmoset to care for twins, help is necessary and a male cooperates both because as a father he gets twice as many of his genes into the next generation with each pregnancy and because they are monogamous, and the male is more certain of paternity than if he lived in a large society where promiscuous matings are the norm. In marmoset and other monogamous New World species, it is not unusual for the father to carry the infant more than the mother, particularly for the first birth (Ingram 1977); although, with subsequent offspring, caring for the infant becomes a family affair, with siblings often carrying the infant as much as the father. This has dual benefits: the infant gets the care it

needs, and the siblings get practice parenting (Cleveland and Snowdon 1984). Studies show that without such practice, as male and female offspring reach adulthood and give birth to their own infant, they are inept as parents and their offspring often perish (Pryce 1993), again illustrating the importance of learning in developing appropriate parenting skills.

Monogamous Old World males of species like gibbons and siamangs also play a significant role in caring for their offspring; however, unlike the *Callitrichidae*, they do not engage in overt parenting from the first day of infant birth. While siamangs begin engaging in parenting earlier than do gibbons, in neither species do males play a primary role during the first year of life. In siamangs, for example, males do not carry their offspring until it is about a year old. However, once siamang males begin carrying the yearling, they may do so more often than the female (Chivers 1972). Among gibbons, fathers have not been observed carrying their infants or sleeping with their infants until they are weaned (Gittins and Raemaekers 1980). In at least one study (Clemens et al. 2008), after the infant gibbon was weaned, fathers spent more time than mothers interacting with their offspring (i.e., showing more play behavior and sharing food) after the first year of life, but mothers were still more likely to retrieve the infant when it cried, while siblings play only a limited role. Unlike the monogamous *Callitrichidae*, gibbon and siamang species do not twin, so it is difficult to find a compelling reason for the increased male involvement. Some have suggested that males invest more in these species because their paternity is more certain than it is in the more promiscuous Old World species.

## Conclusions

With the goal of survival until an individual is capable of reproduction, parenting is considered an investment in continuing the genetic line of an individual. Thus, as Trivers postulates, parenting is a balance between offspring goals of obtaining all the resources they can to promote their survival

and caretaker goals of balancing the investment of their resources to promote offspring survival as well as their own survival. Parenting can be understood in the context of the relative development of offspring at birth and age of reproductive viability, with species that are born with large brains that mainly develop post-natally, that are highly altricial requiring a larger parental investment for a longer period post-natally when compared to species that are born precocial. While there are certainly neurodevelopmental needs that an experience-expectant brain requires, there are wide individual differences in parenting behaviors within a species, with sensitive parenting generally resulting in typical developmental outcomes and abusive parenting leading to negative outcomes, including psychopathologies. While mothers are typically thought of as the primary caregiver across mammalian species, fathers are also known to play a role to varying degrees, dependent on ecological context. Parents are a crucial part of the altricial infant's early experience, with the developmental signature of their caregiving lingering well into adulthood and across generations.

## Parietal Lobe

James W. Bisley  
University of California at Los Angeles,  
Los Angeles, CA, USA

### Definition

The parietal lobe is a region of the human brain defined by anatomical landmarks. Within it are brain areas that process somatosensory information, spatial attention, visual-motor transformations, numerical computations, and language, including reading.

### Introduction

The aim of this entry is to provide an overview of the parietal lobe of the brain. It will cover the basic

anatomy in the human and non-human primate and general neural processing, briefly highlighting the effects of lesions in the human brain and neuronal processing in the non-human primate brain.

## The Parietal Lobe in the Human Brain

### Anatomy of the Parietal Lobe

In the human, the parietal lobe is situated posterior to the frontal lobe, anterior to the occipital lobe, and superior to the temporal lobe (Fig. 1). Several of its margins are defined by clear landmarks. On the lateral surface, it lies posterior to the central sulcus, which separates it from the frontal lobe, and superior to the lateral fissure (also called the Sylvian fissure), which separates it from the temporal lobe. On the medial surface, it lies superior to the cingulate sulcus, which separates it from the limbic lobe, and anterior to the parieto-occipital sulcus, which separates it from the occipital lobe. At the posterior end on the lateral surface, it is separated from the occipital and temporal lobes by two imaginary lines. The first runs from the tip of the parieto-occipital sulcus, which is on the medial aspect of the brain, to the preoccipital notch and separates the parietal lobe from occipital lobe (dashed line, Fig. 1). The second is an imaginary extension of the lateral fissure, which separates the parietal lobe from the temporal lobe.

Within the parietal lobe, there are six main regions: four on the lateral surface and two on the medial surface. On the lateral surface, between the central sulcus and the postcentral sulcus, is the postcentral gyrus (PcG). Poster to this, the parietal lobe is divided by the intraparietal sulcus to form the superior parietal lobule (SPL) and the inferior parietal lobule. The latter is typically divided into two regions: the supramarginal gyrus (SmG) and the angular gyrus (AnG). On the medial aspect of the brain, the postcentral gyrus is contiguous with the posterior paracentral lobule (PPL), which ends at the marginal limb of the cingulate sulcus. Posterior to the cingulate sulcus is the precuneus (Pc), which is an extension of the superior parietal lobule and ends at the parieto-occipital sulcus.

**Parietal Lobe, Fig. 1** The parietal lobe in the human brain. The extent of the parietal lobe is indicated by the colored areas, which are coded based on the regions within

the lobe. *PcG* Postcentral gyrus, *SPL* superior parietal lobule, *SmG* supramarginal gyrus, *AnG* angular gyrus, *PPL* posterior paracentral lobule, *Pc* precuneus

### Functions of the Parietal Lobe

Primary somatosensory cortex lies in the postcentral gyrus, adjacent to the central sulcus. This is the main cortical area to receive information from the body about proprioception (information about body and limb position) and touch. The rest of the parietal lobe is composed of association areas: cortical areas that further process sensory information from one sensory source (unimodal) or from several sensory sources (multimodal). The unimodal association areas tend to be close to their respective primary sensory cortical areas. So somatosensory association areas are close to the postcentral gyrus, and visual association areas are close to the occipital lobe. The remaining areas within the parietal lobe are multimodal association areas.

The parietal lobe is one of the more lateralized lobes within the brain. Many of the multimodal association areas in the human parietal lobe have different functions on the left and right side of the brain. In most people, the left side is the *dominant hemisphere*. Together with the temporal lobe, regions of the inferior parietal lobule in the dominant hemisphere are involved in language comprehension. Lesions of this area produce *Wernicke's aphasia*: patients can have difficulty reading, comprehending speech, writing, or speaking. Deficits in writing or speaking are not motor related, but are due to an inability to put the correct words into a written or spoken sentence.

Lesions around the angular gyrus can also cause computational difficulties.

More dorsal lesions, around the intraparietal sulcus, can produce deficits in visually guided movements. These can include forms of *apraxia*, in which patients have difficulty executing learned and skilled movements, and *optic ataxia*, in which the patient has difficulty in making accurate and appropriate visually guided movements, including the grasping of objects they can recognize and describe. While these deficits are usually seen after lesions of the dominant hemisphere, they can follow from lesions of the nondominant hemisphere.

Lesions in the parietal lobe of the nondominant (usually the right) hemisphere tend to have a striking effect on the awareness of space. Thought to be due to deficits in the mechanisms underlying visual attention, patients can exhibit signs of *hemispatial neglect* or *extinction*. A patient with neglect tends to ignore the spatial world on the contralateral side (usually the left side of visual space). For example, they may draw a clock with the numbers 1 to 12 all on the right side of the circle or they may draw an object, but leave out features on the left side. In severe cases, patients can be unaware that the left side of their body belongs to them. Extinction is a more subtle deficit in which patients do not notice a visual or tactile stimulus on their affected side (usually the left) when simultaneously presented with a similar

stimulus on their intact side, but they are able to notice it when presented alone.

## The Parietal Lobe in the Nonhuman Primate Brain

### Anatomy of the Nonhuman Primate Parietal Lobe

Aspects of the parietal lobe in the nonhuman primate are quite similar to the parietal lobe in the human (Fig. 2). Laterally, the anterior boundary is the central sulcus and the inferior boundary is the lateral fissure; medially, the posterior boundary is the parieto-occipital sulcus. However, the remaining boundaries are not as well established. On the medial aspect, the cingulate sulcus in the nonhuman primate does not curve inferiorly as it does in the human, so we have defined the inferior anterior boundary of the parietal lobe based on where cingulate cortical areas, as defined functionally and cytoarchitectonically, end and parietal cortical areas begin. Laterally, we have placed the posterior boundary of the lobe at the extension of the superior temporal sulcus. The area posterior to the superior temporal sulcus has been identified as the angular gyrus (Martin and Bowden 2000), which in humans is part of the parietal lobe. While this does appear to be the gross anatomical homologue, in terms of cortical areas, it is more homologous with the occipital lobe in the human, so we have not included it as part of the parietal lobe here.

The major regions within the parietal lobe of the nonhuman primate are similar to those in the human. Adjacent to the central sulcus is the postcentral gyrus, the intraparietal sulcus divides the superior parietal lobule from the inferior parietal lobule, and on the medial aspect posterior to the cingulate sulcus is the precuneus. Areas within the SPL and IPL are frequently described as being part of posterior parietal cortex. A key advantage of the nonhuman primate over the human is the ease with which physiological and histological mapping can be done. The regions labeled in Fig. 2 are all made up of multiple brain areas defined in these ways. In the following section, we will list some of the major and better understood brain areas with a brief note about their functions.

### Functions of the Nonhuman Primate Parietal Lobe

Functionally, the nonhuman primate lacks the lateralization seen in the human parietal lobe, but the basic foundations remain. Primary somatosensory cortex is found in the postcentral gyrus along with a number of areas involved in processing somatosensory information. The superior parietal lobule is primarily composed of area 5, which itself can be broken down into a number of areas (PE, PEC, PEip, MIP) based on cytoarchitecture and connections (Pandya and Seltzer 1982). These areas all appear to play important roles in visually guided movements, including visually guided reaching (Breveglieri et al. 2006; Snyder et al. 2000). In some studies, several of these areas close to the intraparietal

**Parietal Lobe, Fig. 2** The parietal lobe in the nonhuman primate brain. The extent of the parietal lobe is indicated by the colored areas, which are coded based on the regions

within the lobe. *PcG* Postcentral gyrus, *SPL* superior parietal lobule, *IPL* inferior parietal lobule, *Pc* precuneus

sulcus are grouped and termed the parietal reach region (PRR). Area AIP, which seems to have a similar function for grasping actions (Sakata et al. 1995), is found at the anterior end of the lateral/posterior wall of the intraparietal sulcus. These areas are likely to be nonhuman primate homologues of the areas that, when lesioned, create apraxia and optic ataxia.

Deep in the intraparietal sulcus is area VIP, a multimodal area which receives visual inputs, somatosensory inputs that appear to come from areas of the body with congruent receptive fields to the visual inputs, and vestibular inputs (Chen et al. 2011; Duhamel et al. 1998). Further, neurons in this area appear to encode numerosity as well. Part of the lateral/posterior bank of the intraparietal sulcus is area LIP, which is thought to be involved in the processing of visual information for the guidance of attention – both covert attention and eye movements (Bisley and Goldberg 2010). It appears to be a more specialized region within area 7, which encompasses much of the IPL. It is likely that these areas are the nonhuman homologues of the areas that, when lesioned, create neglect and extinction.

On the medial aspect of the parietal lobe are continuations of areas within the somatosensory cortex as well as area 7 and PEc. In addition, there are a number of multimodal association areas (such as V6, V6A, and LOP) that integrate visual and somatosensory information (Galletti et al. 1999a; Galletti et al. 1999b). Areas V6 and the ventral aspect of V6A appear to be high level visual processing areas providing visual information for movements. The dorsal aspect of V6A is affected more by somatosensory inputs and is thought to be more closely related to visually guided grasping movements. Each of these areas has strong connections with regions within area 5, including MIP and AIP.

Although the parietal lobe, as seen in the human, is not obviously present in species with lissencephalic brains – that is, brains that do not have prominent sulci – many primate and lower species have homologous somatosensory cortices and posterior parietal cortex areas with multimodal sensory processing to aid in driving motor commands.

### Introduction

Among the areas of the monkey parietal cortex, those lying inside the parieto-occipital sulcus (POs), especially in its anterior bank and fundus, have been of particular interest for neuroscientists in the last decades. In fact, while the areas in the posterior bank show simple low-level visual responses, areas of the anterior bank and on the fundus have complex high-level visual and visuomotor functions. In this chapter, we will describe the main properties of neurons of the areas located in the POs.

### Localization of Areas in the POs

Figure 1 shows in different colors the areas located in the POs. All these areas have been traditionally considered as visual, because all of them contain visual cells. Thus, the names of all these areas start with the letter “V.” In the posterior bank, there are areas V2 and V3 (see Fig. 1a). In the fundus, there is a part of area V6. Areas of the anterior bank include the remaining part of V6 and area V6A. Areas V2, V3, and V6 are part of Brodmann’s area 18 (Brodmann 1909), whereas area V6A is part of Brodmann’s area 19 (Brodmann 1909, see Fig. 1a).

While the localization of areas in the posterior bank of POs is a proved concept (Zeki 1969; Gattass et al. 1981, 1988), the correct localization of areas in the fundus and in the anterior bank of the POs is a challenging issue, because POs has a

very complex and irregular shape. Thus, it is more subject to individual variability of the pattern of brain convolutions. Given these difficulties, there is not a consensus about the nomenclature and borders of these areas (Galletti et al. 2005).

In the 1980s, the anterior bank of POs was considered a single functional area, called PO (Gattass et al. 1985). One year later, Ungerleider and Desimone (1986) called “PO” a region occupying the fundus and part of posterior bank of POs (see Fig. 1b, blue line). Three years later, Colby et al. (1988) reduced the extension of PO to the lower part of the original PO (see Fig. 1b, green line). Later on, Lewis and Van Essen (2000) called “PO” mostly the dorsal part of the anterior bank of POs (see Fig. 1b, red line). Most of the discrepancies between these nomenclatures were because these definitions of PO were based in some cases on functional properties and in others on anatomical grounds.

In the same period of time, another nomenclature was used to define areas in the fundus and in the anterior bank of POs. In 1986, Zeki (1986) used the term “V6” to describe an area containing visual inputs by delimiting it by strong callosal connections. This area occupied almost the entire anterior bank of the POs, thus overlapping considerably with the PO of Gattass et al. (1985). A few years later, Galletti et al. (1996) divided the V6 of Zeki et al. (Zeki 1986) in a dorsal region containing visual and nonvisual cells (called V6A, see magenta area in Fig. 1a) and a ventral region containing only visual neurons (called V6, see green area in Fig. 1a). This latter one is the nomenclature currently used in literature, from 1999 on, also thanks to a wealth of functional and anatomical studies performed in this cortex (Fattori et al. 2017; Gamberini et al. 2015).

### Functional Properties of Areas of POs: Visual Properties

#### Area V2

Area V2 is the secondary visual area and occupies almost all the posterior bank of POs (Zeki 1969; Van Essen and Zeki 1978; Gattass et al. 1981) (see red area in Fig. 1a). All the cells in V2 are visual,

**Parieto-occipital Sulcus (POS), Fig. 1**

Brain location of areas located inside the parieto-occipital sulcus. **(a)** Modern subdivisions of the parieto-occipital cortex. Areas V2, V3, V6, and V6A are shown on 3D reconstructions of a macaque left hemisphere. *Top left and bottom: dorsal view; top-right: postero-mesial view.* Area V2 is represented in red, V3 in orange, V6 in green, and V6A in magenta. **(b)** Historical overview of the location of area PO according to different authors showed in dorsal (left) and on mesial (right) views of a macaque left hemisphere. Abbreviations: *POs* parieto-occipital sulcus, *Ls* Lunate sulcus, *STs* superior temporal sulcus, *Lf* Lateral fissure, *IPs* Intraparietal sulcus, *Cs* Central sulcus, *Cin* cingulate sulcus, *Cal* Calcarine fissure, *a* anterior, *m* medial, *d* dorsal, *l* lateral

and they are mostly activated by small light bars. Overall, the length of the light bars activating V2 is from 0.1° to 15° (Galletti et al. personal communication), but the overwhelming majority (94%) of cells were activated by bars with a length within 5°. The preferred stimulus size of area V2 cells is reported in Fig. 2a. Area V2 is topographically organized (Zeki 1969; Van Essen and Zeki 1978; Gattass et al. 1981) and contains the representation of the entire visual field. As in all striate and extrastriate visual areas, also in V2 there is a strong correlation between the size of the visual

receptive field and the eccentricity, as shown in Fig. 2b (red line).

Besides the sensitivity to the stimulus dimension, V2 neurons are also sensitive to the orientation, to the color (Gegenfurtner et al. 1997) and to the shape of the stimulus (Hegd  and Van Essen 2000; Anzai et al. 2007). V2 neurons respond also to complex visual features, like the orientation of illusory borders and binocular disparity (Thomas et al. 2002; Anzai et al. 2007). Moreover, V2 neurons show choice-related activity (Nienborg and Cumming 2006). A small incidence of V2

**Parieto-occipital Sulcus (POS), Fig. 2** Features of visual receptive fields of areas of the POs. (a) Distributions of the dimensions of the stimuli activating V2, V3, V6, and V6A visual cells. From V2 to V6A, an increase of the effective visual stimuli is evident. (b) Relation between

visual receptive field size and eccentricity in each of the areas of POs. Equations of the regression lines are shown for each area. Receptive field size increases with eccentricity in all the areas, with an increasing trend of the receptive field size from V2 to V6A. Other conventions as in Fig. 1

neurons (14%) are able to distinguish the real motion of a visual stimulus from the self-induced motion (real-motion cells, Galletti et al. 1988). An example of one of these cells is shown in Fig. 3a. It gives a strong response when a visual stimulus moves across the receptive field (Fig. 3a, top), whereas no response is present when the eyes pursue the fixation target moving in the opposite

direction with respect to the stimulus in the previous condition, while the visual stimulus is maintained still (Fig. 3a, bottom). It is noteworthy to highlight that the visual stimulation is the same in the two conditions. Thus, these visual cells are activated by a visual stimulation, but are not responsive if the same visual motion is present on the retina but in presence of eye movements. It

## REAL-MOTION CELLS

**Parieto-occipital Sulcus (POS), Fig. 3** Real-motion cells of areas V2 (a) and V6 (b) (Modified from Galletti et al. 1988; Galletti and Fattori 2003). For each area, a comparison of neural activity evoked by stimulus movement during steady fixation (*top*) and by eye movement against a stationary stimulus (*bottom*) is reported. Spike activity is shown as peri-stimulus time histograms (PSTHs); Horizontal (H) and vertical (V) components of a

typical record of eye movement are reported below spike activity. Scales: neural activity (y-axis), two spikes/division (area V2); 150 Spikes/s (area V6); eye position;  $4^\circ$  per division; time (x-axis), 50 ms/div (a), 100 ms/div (b). Real motion cells respond to a real movement of the stimulus in the visual field, but not to the same retinal movement evoked by eye movements

has been proposed that cells of this kind are involved in the detection of visual motion, taking into consideration also ocular motility (Galletti and Fattori 2003; Galletti et al. 1988).

### Area V3

Area V3 is generally considered a transitional or relay station in the extrastriate pathways and

borders area V2 ventrally (Van Essen and Zeki 1978; Gattass et al. 1988, see Fig. 1a) in the posterior bank and fundus of POs. Like V2, also V3 cells are all visual. The stimuli activating V3 cells are light bars like V2, but their size is generally higher than that effective for V2 (see Fig. 2a). Differently from V2, the dimensions of effective stimuli for V3 cells spread over a larger range of

values (from  $0.4^\circ$  to  $40^\circ$ , see Fig. 2a), and the receptive field size is overall higher than in V2 (see Fig. 2b) at any given eccentricity. Like all the extrastriate areas, in V3 too there is a strong correlation between receptive field size and eccentricity: the higher is the eccentricity, the wider is the receptive field.

Area V3 is retinotopically organized (Van Essen and Zeki 1978; Gattass et al. 1988; Arcaro and Kastner 2015); however, its ventral and dorsal parts, representing the two different visual hemifields (ventral part: superior hemifield; dorsal part: inferior hemifield), have different afferences and functional properties (Desimone and Ungerleider 1986).

Most of V3 neurons (80%) are orientation selective and a minor incidence (about 40%) is directional selective (Gegenfurtner et al. 1997). About half of V3 neurons are sensitive to color (Gegenfurtner et al. 1997). These data suggest that V3 is important in processing higher-level visual signals dealing with motion and also with other visual attributes.

### Area V6

V6 is a visual area located in the fundus and in the ventralmost part of the anterior bank of POs (Galletti et al. 2005) (see Fig. 1a, green surface). All its cells are visual. The strong correlation between eccentricity and receptive field size holds true also for V6 (see Fig. 2b), but the receptive fields are bigger than those of V3. V6 cells are sensitive to light bars and to dark-light borders whose dimensions are widely distributed from  $1.2^\circ$  to  $50^\circ$  (see Fig. 2a).

Area V6 is topographically organized and contains the representation of the entire visual field (Gamberini et al. 2015). V6 cells are very sensitive to the direction, orientation, and speed of motion (Galletti et al. 1996) and elaborate visual information at a high-level order. Indeed also in V6 there are real-motion cells, one example of which is shown in Fig. 3b (Galletti and Fattori 2003). In this cell, there is a strong activation when the visual stimulus moved from right to left, whereas similar retinal stimulations obtained by rightwards pursuit movements, with the stimulus stationary on the screen facing the animal, did not activate the cell. Another complex

elaboration of visual information performed by V6 is the elaboration of heading signals, which are signals about the direction of self-motion (Fan et al. 2015). The majority of V6 cells (91%) are sensitive to heading defined by optic flow stimuli, that is, the pattern of apparent motion of objects, surfaces, and edges (e.g., dots or stars) in a visual scene caused by the relative motion between an observer and a scene. However, almost all V6 cells are unresponsive to inertial motion in the absence of optic flow; thus, they are not modulated by vestibular stimuli (Fan et al. 2015). An example of a V6 cell tested for visual and vestibular stimuli evoking heading sensation is shown in Fig. 4. The example neuron responded most vigorously to optic flow stimuli that simulated rightward translation (Fig. 4, top) but showed no significant sensitivity to vestibular stimuli (Fig. 4, bottom) evoking the equivalent heading sensation. However, V6 does not perform multisensory integration but extracts heading signals basing only on visual information (Fan et al. 2015). Overall, these data confirm that V6 is a high-level visual cortical area.

### Area V6A

Area V6A occupies almost all the anterior bank of POs (Fig. 1a, magenta area) and is the only visual area of POs that contains also non-visual cells (see next paragraph). V6A contains about 60% of visual cells (Gamberini et al. 2015), activated by dark-light borders whose dimensions span from  $3.2^\circ$  to  $50^\circ$  (see Fig. 2a). The receptive field size increases with eccentricity, although less strictly than in V6 (see Fig. 2b). Area V6A contains a coarse visual topography, with the representation of the central visual field in the dorsal part and the periphery mainly in the ventral part (Gamberini et al. 2015). Differently from V6, V6A does not contain real-motion cells (Galletti and Fattori 2003).

### Functional Properties of Areas of POs: Properties Other Than Visual

Despite the majority of V6A cells are visual, V6A is currently more considered as a visuomotor area

**Parieto-occipital Sulcus (POS), Fig. 4** 3D heading tuning for an example neuron of area V6. *Top*, visual stimuli. PSTHs of responses of the neuron to optic flow stimuli simulating 26 heading trajectories in 3D space. *Bottom*, vestibular stimuli. PSTHs are shown for responses of the same neuron to vestibular heading stimuli. Modified from (Fan et al. 2015). The cell discharges for heading information derived uniquely from visual stimuli, being insensitive to equivalent heading signals

rather than a purely visual region. In fact, it contains cells with somatosensory properties and motor-related properties. Figure 5 shows the sensitivity of V6A to passive somatosensory stimulations. Tactile receptive fields are mainly located on the arm, similarly to the location of joints whose rotation activates V6A cells (Fig. 5a, b). An example of a cell modulated by the passive rotation of the shoulder is depicted in Fig. 5c. There is a strong response when the shoulder was passively abducted (the elbow goes far from the trunk) and no response when the shoulder was passively adducted (elbow close to the trunk). About 30% of V6A cells showed somatosensory properties (Fattori et al. 2017).

However, the most effective signals modulating V6A cells revealed to be those related to arm/hand actions to reach objects in space and at interacting with objects. In fact, about 70% of

**Parieto-occipital Sulcus (POS), Fig. 5** Somatosensory properties of area V6A. (a) Body locations of V6A tactile receptive fields. Above the animal, the internal surface of the left arm is reported to show locations of tactile receptive fields in that part of the body. Note that receptive fields are all reported on the right part of the body. (b) Location of joints modulating V6A cells. Each black dot indicates the joint that modulates V6A cells. The size of the dot is proportional to the number of modulated units. (c) Example of a cell modulated by the abduction of the contralateral shoulder. The activity of the recorded cell is shown as PSTH. Bars below the PSTH indicate the duration of shoulder abduction and adduction. Modified from Fattori et al. 2017. Other conventions as in Fig. 3. Area V6A is the only area in the POs showing also responses to passive somatosensory stimulations

V6A cells are reach-related, and most of them show directional tuning (Fattori et al. 2017). Also reaching actions performed at different depths have been shown to influence the discharge of V6A (Hadjidimitrakakis et al. 2014). Besides being a reach-related area, V6A is deeply modulated also by grasping actions. The first

**Parieto-occipital Sulcus (POS), Fig. 6** Grasping neurons in V6A. (a) Episode of naturalistic grasping of food from pliers. The audio band of the video clip below animals' pictures indicates the activity of the recorded cell (vertical bars are action potentials). Horizontal thick bar

over the audio band indicates the period during which the food was presented to the animal (yellow), the period when the animal transported the arm towards the food (green), the time when the animal grasped the food (red), and the period when the monkey brought the food to the mouth

evidence at this regard was obtained by Galletti's lab (Fattori et al. 2004) that tested V6A neurons while monkeys reached to grasp food using naturalistic, nonstereotyped actions. Figure 6a shows an example of one of V6A grasping cells documented in this way. The discharge of this neuron was modulated during the entire act of prehension, as shown in the video frames reported in Fig. 6a. Spike-train frequencies were higher than the baseline activity during food presentation (yellow frame), and a strong discharge rate was maintained during hand transport and finger extension (transport phase, green frame), as well as during finger flexion and food grasping, in the last phase of prehension (grasping phase, red frames). This phase was exaggeratedly long because the monkey made several attempts to grab the raisin in the pincer, continuously trying to catch the food. Neural discharge drastically decreased when the arm began the return movement to the mouth (blue frame). More than 50% of tested neurons were modulated by the entire act of this naturalistic prehension (Fattori et al. 2004). These were the first data about the involvement of V6A in grasping action and paved the way to new experiments to understand more precisely the role of V6A in grasping.

The first quantitative experiment was made when the monkey performed stereotyped movements to grasp a handle that could have different orientations within a instructed-delay grasping task in darkness, so to test neurons with different wrist orientations (Fig. 6b, Fattori et al. 2017). The majority of the tested cells (54%) turned out to be sensitive to the wrist orientation. An example of a V6A cell tested for grasping in light – a

phenomenon recently investigated (Breveglieri et al. 2016) – is shown in Fig. 6c. This cell was tested for four wrist orientations and fired vigorously as soon as the movement started (alignment time) and suddenly decreased the discharge once the handle was grasped. The neural discharge depended on the orientation of the handle (and therefore of the wrist orientation), strongly discharging when the handle was oriented horizontally (hand pronated) and vertically (hand half pronated), and weakly when it was oriented at 135° (halfway half pronated/pronated). As this cell was tested in light, it can be suggested that the vision of the hand-handle interaction, in given wrist orientations, strongly activated the cell.

The study of the involvement of V6A in encoding distal components of prehension continued by testing its neurons when the animals in darkness performed grasps requiring different grip types (Fattori et al. 2017): about 50% of tested cells displayed grip selectivity. Their population discharge, when five different grips are used (Fig. 7a), is shown in Fig. 7b. The activity of each grasping neuron for each of the five tested grips was ranked in descending order to obtain the population response for the best grip, the second best one, and so on, up to the fifth (worst) grip. The plot shows a clear distinction among the activations during the execution of grasping actions (Grasp in the figure). The fact that the curves are already separated before grasping suggests that the neurons began to code the impending reach-to-grasp movement well before the occurrence of the movement itself. The absence of visual information and the occurrence

**Parieto-occipital Sulcus (POS), Fig. 6** (continued) (blue). This cell was modulated during all these phases of the prehension action. Scale bar, 500 ms (Modified from Fattori et al. 2004) (b) Stereotyped grasping test. The monkey was in front of a panel containing an handle and pressed a button close to its chest. Then, a green fixation point was illuminated on the panel and the monkey was instructed to fixate it. Then, when the color of the fixation point changed to red, the monkey had to reach and grasp the handle (Mov) on the panel until the fixation point was illuminated. Then, the monkey came back to the starting

position. (c) Example V6A cell tested with this task in light when the handle was presented with four orientations, requiring four different wrist orientations. This cell shows a strong discharge when the handle is grasped, especially when the wrist is pronated, and half pronated. Scale bar: 85 Spikes/s. Other conventions as in Fig. 3. These demonstrations of modulations in V6A from distal components of prehension were obtained when the grasping was performed in the light, so when the motor-related signals may be added to the visual ones to monitor prehension

**Parieto-occipital Sulcus (POS), Fig. 7** Grip modulations in area V6A. (a) Drawing (derived from videoframes) of the five objects used by the monkey to grasp objects of different shapes. The orientation of the objects was chosen so that wrist orientation was similar in all cases. The different object to be grasped required different hand pre-shaping for the accomplishment of the grip: the ball with the whole hand (leftmost drawing), the handle with fingers only, the ring with the index finger only (hook grip), the

plate with a primitive precision grip with fingers/thumb opposition, and the stick-in-groove with an advanced precision grip with precise index-finger/thumb opposition (rightmost drawing). (b) Grip discrimination in V6A. Population neuronal activity, expressed as averaged normalized Spike density functions (SDFs, *thick lines*) with variability bands (Standard error of the mean; *light lines*), constructed by ranking the response of each neuron for each grip type in descending order according to the

of these modulations even before action execution point to a corollary discharge hypothesis.

Besides being modulated during grasping preparation and execution (grip tuning), V6A cells display also object tuning. In fact, 25% of V6A cells discharges differently depending on the object observed without a subsequent grasping (Fattori et al. 2017). An example of one of these cells is shown in Fig. 7c. This neuron was highly selective for the object, because its discharge was maximal during the presentation of the handle and very weak during the presentation of all the remaining objects. It has been suggested that the analysis of visual features of the object performed by V6A cells may serve to analyze object affordances, which are the potential actions that we can perform on each object. In fact, V6A cells are modulated by the contextual grasping information, that is, the grip type that is evoked by the visual feature of an object (Fattori et al. 2017).

The interplay between visual information on the object and on grasping and motor-related information during grip was studied only recently. V6A cells were tested when monkeys grasped a handle with different orientations, requiring different wrist orientations for grasping, in the dark and in the light (Breveglieri et al. 2016) or grasping objects of different shapes, requiring different grip types (Breveglieri et al. 2017). It was found that the activity of about 80% of V6A cells is influenced by visual information. An example of a cell containing both visual and motor-related signals for grasp is shown in Fig. 8. This cell was strongly activated during preparation and execution of grasping both in light and in dark

conditions, although it discharged more in the light. The cell showed a clear grip sensitivity, discharging more strongly for the preparation and execution of finger prehension, whole-hand prehension, and primitive precision grips (2nd, 3rd, and 4th panels). Like this cell, the majority of V6A neurons incorporate both visual and somatosensory/motor efferent copy signals and integrate them in guiding prehension.

The grasp-related properties of V6A were recently confirmed by the results of decoding analyses that showed that V6A signals could be used to reliably decode objects and grips (Filippini et al. 2017). This is a further confirmation of the involvement of V6A in high-level elaboration of visual and somatosensory information for guiding hand actions. Moreover, these results add area V6A in the list of brain regions that can be used as a source of signals that can drive brain machine interfaces such as robotic arms/hands capable to grasp objects.

## Conclusion

Functional features of neurons of areas located inside the POs show a caudo-rostral trend from the simplest visual properties posteriorly (area V2) to the multisensory and complex motor-related ones anteriorly (area V6A). While areas V2-V3 are typical extrastriate visual areas, areas V6 and V6A show a higher degree of complexity. Area V6 analyses motion information for the purpose of recognizing real motion of objects and self-motion derived from visual signals.

**Parieto-occipital Sulcus (POS), Fig. 7** (continued) intensity of the response elicited during the movement (Grasp). Neuronal activities are aligned with the onset of grasping movement. V6A grasp-related neurons are able to discriminate the different types of grips, as demonstrated by the huge separation between the *red* and *black curves*. It must be noted that grasps were performed in the dark, so the observed modulations have to be ascribed to somatosensory/motor-related signals and not to visual ones. **(c)** Object selectivity during object observation. *Top*, objects tested. *Bottom*, one example V6A neuron selective for objects. Below each display is a record of

horizontal (*upper trace*) and vertical components (*lower trace*) of eye movements. Neural activity and eye traces are aligned (long *vertical line*) on the onset of the object illumination. This cell is selective for objects, preferring the vision of the handle and being mostly unresponsive to all the remaining 4 objects. *Black bars* below PSTH indicate the time of object illumination. *Vertical scale bars* on histograms: 50 spikes/s. Eye traces: 60°/division. Other conventions as in Fig. 3. Object selectivity and grasping selectivity are phenomena demonstrated for V6A, so far unique at this regard in the superior parietal cortex

**Parieto-occipital Sulcus (POS), Fig. 8** Example of the discharge of a V6A grasping neuron to five different grips and to 2 visual backgrounds. *Top*: type of handgrips. *Middle*: PSTHs. Horizontal scale: 200 ms/div. Vertical scale bar on histogram: 60 spikes/s; eye traces: 60°/division. Data collected in the dark are depicted in *black*, those collected in the light are in *red*. *Bottom*: record of horizontal (*upper* trace) and vertical components (*lower* trace) of eye movements, shown with the same alignment as the neural activity. The activity of cells in each plot was

aligned twice, on fixation onset and on arm movement onset (2 continuous vertical lines), with a dashed vertical line indicating the interruption of the trials to obtain the double alignment. The cell contains a grasp-related response influenced by the type of grip and by the presence of visual input. Neurons like this demonstrate the interaction of visual information and of hand movement signals occurring in the same V6A single cell. Modified from Breveglieri et al. 2017. Other conventions as in Fig. 3

Area V6A contains all the neural apparatus to monitor prehension actions. Specifically, V6A is modulated by prehension from object presentation up to action preparation and execution, with an evolution indicating that V6A processes vision for action (Fattori et al. 2017). Recent works suggest that arm movement sensitivity is higher than visual-related sensitivity and this may suggest that despite its name starting with the letter “V,” V6A should not be counted among the extrastriate visual areas, but among the posterior parietal grasping areas.

## Parkinson's Disease

Raymond Turco

Hunter College, New York, NY, USA

## Synonyms

Paralysis agitans; Parkinsonism; PD; Shaking palsy

## Definition

A progressive and degenerative neurological disorder of movement marked by tremors, postural instability, rigidity, and slow movements.

## Introduction

Parkinson's disease is a chronic and relentlessly progressive disease marked by tremors, muscular rigidity, slow movement, and postural instability. Psychiatric problems, such as depression, dementia, and psychosis, may be comorbid to the illness or to a side effect of treatment. Parkinson's is idiopathic and there is no cure, though pharmacological therapy and potentially brain surgery may lessen symptoms (Binder et al. 2009).

## Symptomatology

Parkinson's is recognized for its classic triad of motor symptoms: a resting tremor, rigidity, and bradykinesia (slow movement). The tremors tend to start in the hands, feet, or jaw at 4–6 Hz, start

on one side of the body, but eventually progresses to encompass the whole frame. Tremors in the hands are notable for what is called a “pill-rolling tremor”, a rhythmic rubbing and shaking of the forefinger and thumb. Tremors are present at rest and dissipate with intentional movement; sometimes, they can be aggravated by stress. Muscle rigidity in swinging arms presents as short and jerky movements as opposing muscle groups fail to communicate properly and thus remain contracted. This results in stiffness and pain for the patient. Facial rigidity can inhibit the communication of emotions and present as a taut, mask-like face. This triad of bradykinesia, muscle rigidity, and tremors makes daily activities such as dressing and brushing one's teeth very difficult for the patient. In advanced PD, postural instability and issues with balance can lead to frequent falls. Moreover, the progression of Parkinson's leads to the worsening of motor symptoms over time. As patients attempt to keep their balance in later stages, they may present with festination, or the hurrying of steps as they propel themselves forward in walking. Freezing, or the sudden cessation of movement, may also occur in later stages. Though Parkinson's is primarily considered a disorder of movement, other non-movement symptoms can present themselves and do often complicate the lives of PD patients. Autonomic dysfunction, a decrease in olfaction and taste, mood disorders, sleep disturbances, diminished elements of cognition, and a high risk to dementia in later stages have all been as issues in those with PD (Double and Finberg 2016).

Parkinson's Disease Dementia (PDD) indicates a decline of cognitive functioning that develops over 1 year post-diagnosis, and may be related to Lewy bodies dementia. It is estimated that some 40% of Parkinson's patients struggle with dementia. Risk factors for developing this dementia include advanced age, a later disease onset, a history of smoking, a history of depression, and a poor response to L-Dopa. Deficits in executive functioning and bradyphrenia, or a slowness of thought processes, have both been noted as prominent issues (Kraybill and Suchy 2011).

## Etiology

The etiology, or cause, of Parkinson's disease is very complex and involves multiple factors that may differ widely across patients. Environmental factors have long been suspected, and at one point, viral infection was hypothesized as a cause of idiopathic PD due to a similarity of symptoms involving viral encephalitis. Though the etiology of Parkinson's as related to a number of diverse environmental risk factors remains controversial, a convincing link to a family history of Parkinson's has been demonstrated, suggesting a possible genetic component. Parkinson's disease as a result of one of six genetic mutations has been seen to develop, yet the treatment for genetic Parkinson's is the same as the treatment for common idiopathic Parkinson's. Nevertheless, studies of genetically-transferred Parkinson's patients and their affected family members have provided considerable insight into the neural mechanisms behind the idiopathic form of the disease (Double and Finberg 2016).

## Pathology

Parkinson's neurological presentation is rooted in the dysfunction of the basal ganglia and cerebellum. Subcortical changes, such as the slow loss of dopaminergic neurons in the substantia nigra region of the basal ganglia, are more notable first, followed by cortical changes later in the disease process, which supports the evidence that demonstrates motor symptoms arising earlier than other symptoms. A deposition of Lewy bodies in both subcortical and brainstem areas, such as the substantia nigra, locus ceruleus, nucleus basalis of Meynert, dorsal medial nucleus of the vagus nerve, and hypothalamus, has been recorded in PD patients, though Lewy bodies are certainly not a unique feature in Parkinson's. Alpha-synuclein accumulation in the basal forebrain and ascending pathways, leading to changes in acetylcholine, has been implicated in the cognitive changes in Parkinson's and the onset of Parkinson's dementia (Cook 2017).

## Prevalence

The prevalence of Parkinson's approaches 1% of the total population by age 65, and 2–3% by age 80. Early-onset Parkinson's, diagnosed before age 40, accounts for around 10% of all Parkinson's cases, a statistic that often goes overlooked (Baron 2011). The gender split is roughly 1:1.5, female to male, and as suggested above, age is a major risk factor. Smoking tobacco has been shown to reduce the risk of developing PD (Schwarz and Storch 2009).

## Assessment

A clinical diagnosis of Parkinson's is made after an examination of patient history plus an important physical and neurological battery, conducted by a neurologist, that involves tests for retropulsion and gait monitoring among other diverse measures. Making a differential diagnosis involves weeding out some of the following illnesses, with their distinguishing features in parentheses: cortical basal degeneration (often with unilateral apraxia and reflex myoclonus), multiple system atrophy (prominent ataxia and autonomic disturbances), progressive supranuclear palsy (issues with vertical eye movement), Wilson's disease (dystonia and liver disease), and Huntington's disease (choreiform movements and family history). A diagnosis of Parkinson's becomes increasingly more probable especially after positive response to levodopa treatment (Cook 2017).

Some presentations of parkinsonism may not be caused by Parkinson's itself, but rather by a psychogenic or pharmacological stimulus. Parkinsonism may stem from a conversion or somatoform disorder or be caused by neuroleptic (dopamine antagonist) therapy used to treat psychotic disorders. However, the Parkinson-like presentation of those who ingest neuroleptics over a long period of time is often bilateral as opposed to the asymmetrical presentation of Parkinson's. Diagnosis of the disease and the gauging of severity are facilitated by one of two standard rating scales: the modified Hoehn and

Yahr Scale or the Unified Parkinson's Disease Rating Scale (UPDRS). Post-mortem examination for Parkinson's tends to confirm the diagnosis at a rate of about 80% of those diagnosed with Parkinson's in life (Cook 2017).

## Treatment

Treatments for Parkinson's disease include a wide range of pharmacological therapies, as well as surgery.

### L-Dopa

Levodopa is the amino acid precursor to dopamine that is synthesized by many plants and animals, including humans. Whereas the neurotransmitter dopamine cannot cross the blood-brain barrier, L-Dopa can. It was first implemented in the 1960s and has remained the first-line treatment for PD to this day. L-Dopa works to increase the levels of dopamine in the surviving nigrostriatal neurons of the basal ganglia. It cannot cure PD, yet it can mitigate motor symptoms in the mild to moderate stages of the disease. The short half-life of L-Dopa necessitates that the patient take regular, evenly-spaced doses throughout the day. Historically, L-Dopa was prescribed orally on its own, with only minimal transference across the blood-brain barrier, thus necessitating very high doses and causing unpleasant side effects like vomiting and nausea. Today, either carbidopa or benserazide, two inhibitors of DOPA decarboxylase, are combined with levodopa to increase its absorption into the brain and reduce these side effects. After some years of symptom reduction with levodopa treatment, the disease progresses and the dosage must be increased to compensate for a continual death of dopaminergic neurons. Elevated levodopa doses are also associated with such side effects as constipation, hypotension, lethargy, hallucinations, and confusion. Dyskinesia, involuntary twisting movements of the arms, legs, and trunk, can result after long-term levodopa therapy. Duodopa pumps that continually pump levodopa into the body have been implanted in recent years to some success (Double and Finberg 2016).

### Glutamate Receptor Antagonists

Glutamate receptor antagonists may be beneficial in the treatment of LID, the dyskinesia associated with levodopa therapy, yet not without a number of pronounced side effects. Nevertheless, with the wide diversity in glutamate subtypes and their distribution across the brain, researchers have not stopped the search for new and selective drug possibilities on this front. The main drug of this class currently in use to treat PD is amantadine, an antiviral with anti-glutamatergic properties (Double and Finberg 2016).

### Dopamine Agonists

In order to alleviate motor symptoms in the later stages of the disease and compensate for the lack of surviving dopaminergic neurons, dopamine agonists are used to directly stimulate the dopamine receptors themselves. Dopamine agonists work by stimulating D2 and also D1 receptors and are primarily taken orally. The side effects associated with dopamine agonists are virtually analogous to those associated with levodopa, though levodopa is considered more effective at treating symptoms than any dopamine agonist. However, elevated doses of L-Dopa combined with long-term treatment have been associated with increased cell death due to the presence of uncontrolled free radicals. To combat this phenomenon, dopamine agonists and levodopa are sometimes given in tandem in order to reduce the dosage of levodopa and transfer some of that burden onto the stimulation of dopamine receptors by the dopamine agonists (Double and Finberg 2016).

### COMT Inhibitors

Catechol-O-methyl Transferase, or COMT, is a widespread enzyme that serves to break down dopamine, and COMT inhibitors impede this breakdown as a second-line medication for the treatment of Parkinson's (Binder et al. 2009; Double and Finberg 2016). Tolcapone and entacapone are the two drugs available of this type. Entacapone inhibits COMT only peripherally and thus does not cross the blood-brain barrier, unlike tolcapone. The inhibition of COMT in the periphery reduces the metabolism of L-Dopa

there, which augments the availability of the drug to the brain. Though tolcapone can cross the barrier and improve the brain's response to L-Dopa by reducing the metabolism to dopamine, there is a significant risk of toxicity to the liver that limits the non-clinical diffusion of this medication. Thus, a common combination of medications for the treatment of Parkinson's is entacapone, L-Dopa, and a previously-mentioned peripheral inhibitor of AAAD, like carbidopa (Double and Finberg 2016).

### Deep Brain Stimulation

Deep Brain Stimulation (DBS) involves the implanting of electrodes to stimulate the important areas of the basal ganglia that are most affected by Parkinson's. Detailed electrophysiological studies of the brain's circuitry and interaction between the pallidum, thalamus, and the motor cortex allowed for the development of this technology, as it became apparent that high-rate electrical stimulation could correct the hallmark motor symptoms of the disease. With the proper equipment, the procedure can be performed in any department of neurosurgery. The implanted electrodes connect to a battery-operated stimulator under the patient's skin, which can be controlled by the patient with a remote, much like a pacemaker for the heart. The procedure is best-suited for those who suffer from an early onset, who are in an advanced stage of the disease, or who do not respond satisfactorily to L-Dopa, and can tolerate the stress of neurosurgery. There are great improvements for many, but the complications can include hardware difficulties and some psychiatric and neurological side effects (Double and Finberg 2016).

### Future Directions in Treatment

Attempts have been made to introduce human embryonic dopamine neurons to be implanted into the Parkinson's brain as a form of treatment. Results in this area have been frustrated by ethical concerns and a lack of satisfactory clinical trials, with side effects that include dyskinesia. Nonetheless, developments in the ideas of stem-cell research continue to be made (Double and Finberg 2016).

Gene therapy, by way of a gene transfer that increases dopamine synthesis or protects the already-existing dopaminergic cells, is a major new frontier in the fight against Parkinson's. This therapy avoids the inherent problem of L-Dopa needing existing presynaptic neurons to encourage dopamine stimulation and involves using a viral vector to introduce new genes into relevant areas of the brain. Early clinical trials are promising and import some benefits to patients. Alternatively, neurotrophic factors such as glial cell line-derived neurotrophic factor (GDNF) can be delivered through genes to bolster dying neurons, yet concerns about safety have led to cautious progress (Double and Finberg 2016).

## Conclusion

Parkinson's disease is a debilitating and pervasive neurodegenerative condition and, while pharmacological and surgical treatment can slow progress, there is no cure. The restoration and protection of neurons affected is a primary target of investigation, and developing a response to the disease pre-clinically, before symptoms occur, is of particular attention to researchers.

## Definition

Parsimony is a principle used as a means of keeping explanations as simple as possible by providing the simplest of explanations to describe an observation or an understanding.

## Introduction

Behavior is the way in which a living organism reacts to a particular situation. In psychology, behavior is thought of as an organism's external reactions to its environmental stimuli. The analysis of behavior is a science based on the foundations and principles of behaviorism. It can be said that behavior is that particular response of an organism which reflects the kind of stimuli received from the environment. This behavior may be modified by using either positive or negative or manipulating reinforcements from the organism's environment or according to self-directed intentions or impulses. Human behavior is more complex than animal. Society and culture plays a vital role in shaping human behavior although it is difficult to quantify the extent to which it influences behavior.

Behaviorism is a learning theory that only focuses on objectively observable behaviors and discounts any independent activities of the mind. Behavior theorists define learning as nothing more than the acquisition of new behavior based on environmental conditions (Philips and Soltis 1998). So here, we will discuss the role of the most established principle of parsimony in making conclusion regarding the causes of behavioral and cognitive/learning modifications.

Behaviorists identified conditioning as a universal learning process in different experimental efforts and found two different types of conditioning; each yields a different behavioral pattern. The first one is classical conditioning in which a natural reflex responds to a stimulus. Ivan Pavlov (1890) discovered it during his famous experiment with dogs. Every time Pavlov fed a dog, he rang a bell. Pavlov then rang the bell without feeding the dog, and the dog salivated at the sound of the bell. Pavlov had conditioned the

dog to respond to the bell by salivating. Pavlov's experiment served as the one of the cornerstones of behaviorism (Powell et al. 2001). The other one is behavioral or operant conditioning sometimes also called as instrumental conditioning where a response to a stimulus reinforces or operates through reward for good behavior and punishment for bad behavior.

An eminent behaviorist, B.F. Skinner, in 1977 used reinforcement techniques to teach pigeons to dance and bowl a ball in a mini-alley. Therefore, operant conditioning is a simple feedback system where reinforcement follows the response to a stimulus and then the response becomes more probable in the future (Epstein and Medalie 1983). Thus, behaviorism is based upon the idea that all behaviors are acquired through conditioning, via interaction with the environment. For example, in behavioral psychology, by applying the basic principle of conditioning, people who suffer from psychological disorders are retrained, while cognitive psychology deals with the acquisition, processing, and storing of information in the mind. These mental functions include learning, attention, memory, reasoning, conceptual development, language acquisition, perception, and decision-making.

According to Division 25 of the American Psychological Association, analysis of behavior can be done in three different ways:

- Firstly, through the experimental investigation of behavior, i.e., by manipulating the environment under control conditions
- Secondly, through applied behavior analysis (ABA), i.e., by applying the learning behavior principles to real-world situations to change the behavior
- Finally, through the conceptual analysis of behavior which addresses the philosophical, historical, theoretical, and methodological issues in behavior analysis

All of these three areas of behavioral analysis implicate the fundamental principles, theories, and concepts, which are already well illustrated in the area of animal cognition and behavior. In each area of analysis, to test the economy of

explanations involved in the analysis, parsimony plays its pivotal role instantaneously.

## What Is Parsimony?

Parsimony is the well-established basic principle in the study of animal behavior, and in science, this principle is applied as discovery tool that guides researcher for the development of scientific models (Epstein 1984). The law of parsimony is introductory to all scientific disciplines and philosophy and in other applications that use logic (Anderson 1978). Parsimony is frequently equated with Occam's razor, the law which stresses choosing simpler explanations if that simpler explanation fits in totality to the collected data. Therefore, the term parsimonious means the simplest explanation or theory with the least assumptions and variables but with the greatest explanatory power.

Further, the law of parsimony is accepted as an important criterion in science for judging the merits of a theory or an explanation, but it is not the only one. A theory, which is parsimonious, need not be "right" – that is to say, it may not be the most effective or useful description of the body of facts for which it is said to account (Sober and Lewontin 1982).

## Examples

If one finds that, while exploring the causal factors that generate phenomenon Z, causal factor A accounts for 30% of Z, causal factor B accounts for 50%, and causal factor C accounts for 20%, we can conclude that  $Z = A + B + C$  and not worry over additional causal factors so long as the observed evidence is fully accounted for. To elucidate this idea, let's take one more concrete example. Suppose Meera is trying to understand why her pencil falls to the ground when she lets it go from her hand. After some basic research, she concludes that Newton's laws of gravity can fully explain this phenomenon of interest. Meera's friend Danny, however, suggests that while the

laws of gravity are responsible for some of the pencil falling to the ground, there also exist millions of invisible leprechauns that catch falling objects and guide them toward the ground. Danny and Meera both provide explanations of the same natural phenomenon, but Danny's explanation adds unnecessary causal factors. In addition, Danny's explanation is also very difficult to falsify, even though there is no evidence to support it. One hundred percent of Z can be accounted for by A (gravity), thus adding B (invisible leprechauns) adds nothing to our understanding of why the pencil falls to the ground. Because it adds nothing, parsimony suggests we drop it from our equation (Benjamin 2018).

Hence, parsimony is economy in the use of explanation in conformity with Occam's razor. Thus, scientifically, parsimony dictates that any example of animal behavior should be interpreted at its simplest and at the most immediate level. It can be done by adding the smallest number of unsupported assumptions, by postulating the existence of the fewest entities and finally by citing the fewest unobservable constructs the simplest explanation

The law of parsimony is also termed as principle of economy or principle of parsimony. The principle of parsimony argues that the simplest of competing explanations is the one that is most likely to be correct. Moreover, this simplest explanation is not considered an undeniable means of deriving the logic or scientific results but affects the importance of simplifying explanations.

The first statement about this principle is credited to a fourteenth-century English scholastic and philosopher William of Ockham. He proposed a rule of logic that is called "Ockham's razor" (Sober 1994).

By illustrating, an example of pet's responsive behavior in specific circumstances could be better explained by behaviorists with the principle of parsimony (Thorndike 1911).

For example whenever a person goes out of town leaves her dog, Mason, with a close friend. Mason always defecates overnight in one particular spot in friend's house. Mason will

occasionally do this at her home, but not on a regular basis, and the dog is quite familiar with both friend's and her home. She could not figure out any possible reason why Mason would be doing this and therefore concluded that it had to be because Mason was mad at her for leaving him. The reason behind this common tendency to jump on anthropomorphic explanations as the most likely reason for a pet's behavior could be because they believe that these are the simplest explanation for their pets' behaviors while in the point of behaviorists view it is the most complex one.

What might be some simpler explanations for Mason's behavior? Mason's schedule might be different in friend's home, causing his patterns of elimination to shift. Her friend might not be in the habit of giving Mason a last potty break right before bed, or perhaps Sarah is giving him more treats than he usually gets at home. Mason might be afraid to go outside at friend's place because of even one experience with a startling noise. Mason might be a bit anxious away from owner, even though Sarah is familiar to him. Perhaps, Mason doesn't like the texture of what is available for elimination in the yard (Cherry 2018).

Therefore, the principle of parsimony emphasized that the simplest explanations are more straightforward than the other higher thought processes, which could be thought for nastiness to be the motivation for Mason's defecation.

Debate on nature vs. nurture is one of the oldest philosophical issues within psychology. However, while we discuss about parsimony, nature versus nurture argument empowers the explanation of parsimony principle. The debate starts with certain basic question on behavior like the following: Do genetic or environmental factors have a greater influence on our behavior? Do inherited characters or life experiences play a greater role in shaping our personality?

To get answers to these queries, one must understand the meaning of nature and nurture. Nature refers to all of the genes and hereditary factors, while nurture refers to all the environmental variables including our childhood experiences, how we raised our social relationships, and our surrounding culture. It focuses on the relative

contributions of genetic inheritance and environmental factors in human evolution (Breed and Sanchez 2010).

Earlier, a very one-sided approach suggested nature was more important which played pivotal role in the development, while other side suggested that nurture was more significant. Certain philosophers like Plato and Descartes in 2001 suggested that certain things are inborn that they occur naturally regardless of environmental influences, while according to John Locke everything that we are and all of our knowledge are determined by our experience. Theorist John B. Watson in 1915 believed that people could be trained to do and become anything regardless of their genetic background.

An instance of nature versus nurture argument could be that if a man abuses his wife and kids, is it because he was born with violent tendencies or is it something he learned by observing his own parent's behavior? Another example is that all children are born with an instinctive mental capacity that allows them to learn and produce language but the behavior of a child is influenced by parenting styles and by learning through observation and reinforcement. While considering the views of both sides, the simplest and meaningful explanation of this argument is that genetic factors and environmental factors do play their role together and affect each other in a significant way, and researchers are looking forward for the factors and processes that influence their interactions. The reality is that there is no simple way to unravel the intermingled interactions of genetic factors and environmental factors such as social experiences and overall culture. The genetic factors interact with one another and modulate the influences of environmental factors.

As one school of thought, all differences between men and women are believed to be caused by societal and patriarchal forces. Again, societal influences on behavior are evident, and varying cultural gender labels have had profound and often negative impacts (particularly for women) on individuals throughout history. However, to suggest that all gender differences are the result of societal pressures lacks both parsimony and is

factually wrong. What's more, it offers the potential to be a useless and unproductive interpretation to adopt in many situations. Additionally, for example, the defensive behavior of women avoiding driving in risky areas can be explained by the fact that males of nearly all species are more likely to engage in risky behaviors in all facets of life. There would no need to change what is objectively a very smart and rational behavioral decision. The thought arguing about societal factors that they claim cause gender differences in this specific instance is simply wrong and reflects poorly on the general validity of the feminist movement and the important issues the movement seeks to address. Thus, viewing through the lens of law of parsimony, it must be suggested that the gender-specific protective and defensive behavior of women is the main behavioral cause for this and not any other (Benjamin 2018).

There are occasions where one can predict with confidence that a parsimonious theory is likely to be wrong. For example, Anderson in 1978, a cognitive psychologist, has noted that the most "parsimonious" computer program will probably not be the best one to represent cognition. There is no criterion of parsimony in evolution; redundant and supernumerary organs and mechanisms abound in nature. Further, there is no reason to believe that human cognition – or its counterpart in the real world, the nervous system – has been spared nature's disinterest.

## Conclusion

The principle is itself, ironically, an assertion, one that pervades science but that remains, for the most part, unexamined by scientists themselves. Since it is a criterion by which a theory is judged to be better or worse than another, it may have more value (Walsh 1979).

The principle of parsimony may be nothing more than an instantiation of the principle of "least effort," and hence we might interpret Mach's "least possible expenditure of thought" literally (Walsh 1979).

The argument in above examples is about gender differences where parsimony must be

considered in the reasoning. It is also suggested that it should not add causal factors that add nothing to explain the phenomena, especially if the behavior can be fully explained in their absence.

## Partial Reinforcement Extinction Effect

Wendy A. Williams  
Department of Psychology, Central Washington  
University, Ellensburg, WA, USA

## Synonyms

[Intermittent reinforcement](#); [Paradoxical extinction effects](#); [Resistance to extinction](#)

## Definition

The use of partial (i.e., intermittent) reinforcement tends to strengthen both the target behavior and its persistence in the absence of reinforcement. The result is that behaviors that produce only periodic reinforcement tend to be more resistant to extinction than behaviors that have been reinforced continuously.

## Introduction

Partial reinforcement (PR) means responses are only reinforced periodically; continuous reinforcement (CRF) means that every response is reinforced. There are a variety of PR schedules that have different effects on response patterns (see ► [“Instrumental Conditioning”](#)). The partial reinforcement effect (PREE) occurs when operant responses that have been reinforced

only occasionally become resistant to extinction compared with behaviors that have been reinforced continuously. This effect is considered paradoxical since intuition would suggest that behaviors that are reinforced less often should be easier to extinguish.

In the real world, intermittent reinforcement is associated with very persistent responding in extinction. Gambling is the classic example of unpredictable PR and resistance to extinction. Chronic gamblers only receive “payouts” periodically and they may not be particularly large. But the gambler persists despite long stretches with no reinforcement at all. This phenomenon allows gambling houses to bias the profits in their favor. Small to medium payouts in the short run are sufficient to maintain the persistent risk-taking behavior that results in long-term profits for the gambling house.

Several theoretical explanations have been offered and tested to determine the underlying mechanism that produces the PREE.

## The Discrimination Hypothesis

One possible cause of the PREE could be the difference in discriminability of the change in contingency from CRF or intermittent reinforcement to extinction. If a reinforcer follows every response in a one-to-one ratio, the shift to extinction would be very salient. The change in the response-reinforcer contingency would be easily and rapidly detected. Frustrated by the sudden absence of reinforcement, the subject gives up and stops responding. On the other hand, PR is characterized by non-reinforcement on many trials. Only occasionally does a response produce a reinforcer. During training, the subject gradually learns to expect reinforcement less frequently and less reliably. When the contingency shifts away from PR to extinction, it is less discriminable, more difficult to detect, and, as a result, extinction proceeds more slowly.

Jenkins (1962) and Theios (1962) tested the discrimination hypothesis using different species (domestic pigeons, *Columba livia*, and rats, *Rattus norvegicus*, respectively). In both studies,

one group of subjects was trained to respond using CRF. A second group of subjects was initially trained using PR and then moved to a CRF schedule. Once both groups were responding reliably under CRF, an extinction schedule was imposed. Jenkins and Theios reasoned that if the ability to discriminate the change to extinction determines the rate of extinction, responding for both groups should decline at the same rate. Furthermore, extinction should be relatively rapid because the discrimination is an easy one. In both studies, those animals initially trained with PR showed significantly slower extinction than those with CRF experience only. Discriminability differences in the shift from CRF or PR to extinction were not sufficient to explain the PREE phenomenon.

### The Frustration Theory

The frustration hypothesis of PR (Amsel 1958, 1962, 1967, 1992) suggests that extinction is generally the result of emotional frustration that arises when reinforcement is terminated. It proposes that the individual who experiences PR learns to deal with the frustration of non-reinforcement during training. Typically, intermittent schedules are thinned gradually; inter-reinforcement intervals are initially short and gradually lengthen over time. Learners working on a CRF schedule only (e.g., lever pressing or keypecking) do not have the opportunity to learn about non-reinforcement. They become easily frustrated when the reinforcer is omitted. This frustration usually results in a decrease or complete cessation in responding, perhaps due in part to the learner engaging in exploratory or alternative foraging-related behavior (Adelman and Maatsch 1956). PR learners experience the same frustration early in training, but they are quickly moved to and maintained on increasingly leaner intermittent reinforcement schedules. These participants learn that some trials are followed by reinforcement while others are not. Every new trial has a certain probability of reinforcement or not, but reinforcement eventually does occur. When a

reinforcer is delivered, it strengthens both the response itself and the persistence of that response in the absence of reinforcement. As a result, subjects learn to replace the initial frustration with response persistence until reinforcement does occur.

Recently, frustration theory and its effects on persistence during appetitive extinction have been applied to alcohol self-medication during extinction. Manzo et al. (2015) tested rats in a discrete trials runway study. Rats ran for either continuous (CRF) or partial reinforcement (PR) at the end of the runway. After completing the runway test, they were returned to home cages where they freely chose between two water bottles: water/water or water/2% ethanol solution. At baseline, all of the rats showed no preference for ethanol over water. Following initial testing, trials were conducted in which food was removed from the end of the runway. Termination of food reinforcement in the runway (aka extinction) produces emotional frustration, according to Amsel's frustration theory. Rats trained using PR food schedules showed greater runway persistence than the CRF group. Furthermore, the CRF rats developed stronger preferences for the ethanol during extinction than the PR rats. These data suggest that the anxiety or frustration associated with extinction from a CRF schedule will likely produce more self-medicating behavior than a PR schedule would. Torres and Papini (2016) suggest that individuals who experience negative emotions like frustration may self-medicate. In a review of studies like the Manzo et al. (2015) study, they established connections between reward loss, frustration, and self-medication in animals. Such findings are clinically relevant for humans with drug and alcohol addictions.

### The Sequential Theory

The sequential theory (Capaldi 1967, 1971, 1994) proposed a more cognitive explanation for the PREE. It assumes that subjects remember whether or not their behavior has been reinforced

on recent trials. CRF learners recall only that their behavior has always produced reinforcement. They never develop a memory for what happens after non-reinforced trials (because they don't have those experiences). On the other hand, PR subjects remember the sequence of events that follow non-reinforced trials. The probability of reinforcement increases with each successive non-reinforced trial. As such, non-reinforcement becomes an excellent predictor that the next response has an increasingly higher probability of reinforcement and that the next response will pay off increases with each successive no-food trial. The sequential theory argues that it is this ability to remember reinforcement patterns and to be sensitive to reinforcement probabilities that leads to response persistence during extinction with PR subjects. CRF subjects never develop a memory for reinforcement following no-food trials. In this scenario, no-food trials predict nothing about future reinforcement for the CRF subjects. But for the PR learner, no-food trials are highly predictive of future reward.

Haddad et al. (1980) tested the sequential theory using both a CRF group and two partial reinforcement groups that differed only in the sequence of reinforced (R) and non-reinforced (N) trials (e.g., NRRR or RRRN). The sequential theory predicts the formation of an association between non-reinforced responses and subsequent reinforcement for continued responding. This association is not possible in the RRRN condition. Therefore, the sequential theory predicts greater resistance to extinction in the NRRR condition. The results were consistent with the theory's predictions for both the rats and the pigeons.

### **Momentum Theory of Extinction Resistance**

Nevin and Grace (2005) and Nevin et al. (2001) have offered an alternative theory of response persistence under conditions of extinction. Borrowing from momentum theory in physics that says that an object with greater momentum is

harder to stop than one with less momentum, Nevin and Grace suggest that a behavior with greater momentum will resist extinction more than a behavior with less momentum. Behavior momentum is directly related to rate of responding, but not to the rate of reinforcement. Put simply, there is an analogy between velocity in physics and response rate in behavior. A high rate of responding produces greater momentum, and will be more resistant to change. Other findings show that momentum is also sensitive to other factors, such as response-reinforcer relations (Lattal 1989), delayed reinforcement (Bell 1999), and preference (Bell & Williams 2002).

### **Other Paradoxical Extinction Effects**

Two other paradoxical extinction effects have been noted (Domjan 2015): the magnitude reinforcement extinction effect and the over-training extinction effect.

### **The Magnitude Reinforcement Extinction Effect (MREE)**

The magnitude reinforcement extinction effect (MREE) is paradoxical because larger reinforcers do not lead to greater resistance during extinction; rather the opposite appears to be true. Hulse (1958) and Wagner (1961) reported that the use of larger reinforcers led to faster extinction when compared with smaller reinforcers. Similar to Haddad et al. (1980), Capaldi and Lynch (1968) found that N-R transitions with large reinforcers produced greater resistance to extinction than similar N-R transitions with smaller rewards.

While initially seeming paradoxical, it can be easily understood when we think about it in human terms. If your old boss was in the habit of giving very large holiday bonuses, you are likely to respond badly when your new boss only sends out holiday cards. In fact, you might not work as hard or may even change jobs (aka complete extinction). But, for those workers whose bosses give small bonuses, the change to cards only is small and unlikely to result in a

decline in work effort or resignations. The same is true with animals: the degree of contrast in the change from “large to none” is likely to produce more rapid extinction in the first case and slower extinction than when the change is from “small to none.” Although paradoxical at first glance (e.g., larger is better and should make behavior stronger), it is easy to see how the opposite may be true in terms of resistance to extinction.

## The Overtraining Extinction Effect

Overtraining is characterized as a long period of extended training, typically with high levels of precision for the instrumental response. At first glance, it would appear that extended training should establish a strong resistance to extinction. For example, consider the dolphin trained extensively on a complex series of behaviors (e.g., a behavioral chain). Early in training, non-reinforcement will encourage response variability that can be used to shape the desired behavior and increase precision of the response (s). But as the animal masters the behavioral sequence, non-reinforced trials occur less frequently or not at all. Extended training consists of long bouts of behavioral responses with few errors and a virtually continuous pattern of reinforcement. One might predict that it would produce very strong behavior. But when faced with extinction following extensive training with nearly perfect precision, non-reinforcement is a huge contrast. A rapid decline in responding during extinction is not surprising. Because overtraining leads to greater expectation of reinforcement, sudden non-reinforcement produces greater frustration and much more rapid extinction of the behavior than is observed with shorter, less frequent training sessions (Ishida and Papini 1997; Senkowski 1978; Theios and Brelsford 1964; Thombaugh 1967; Pert and Gonzalez 1974).

## Limitations

The paradoxical effects of PR on extinction have been observed in many mammal species, including rats, gerbils, opossums, pigs, monkeys,

and humans (Papini 2003). Papini argues that response persistence during extinction after PR is specific to mammals. He offers neurological correlates of emotion, frustration, and aggression as mediating variables for the effect, specifically the activation of the hypothalamic-pituitary-adrenal axis. He argues that there is an absence of both the PREE and those same neurological structures in fish, amphibians, and reptiles. Behaviorally, resistance to extinction following PR is well established in birds, specifically in laboratory pigeons (*Columba livia*) (Jenkins 1962; Nevin and Grace 2005; Nevin et al. 2001; Roberts et al. 1963). Furthermore, Romero and colleagues have studied the same neural structures in avian species (Romero 2006; Romero and Wikelski 2006; Romero and Wingfield 2001). Thus far, the evidence of PREE effects appears to be restricted to mammals and birds only.

With the magnitude reinforcement extinction effect and the overtraining effect, inverse relations between the amounts of reward and overtraining and extinction also seem to be primarily localized to mammals. Attempts have been made to establish MREE effects of PR in non-mammals, including goldfish, *Carassius auratus* (Gonzalez et al. 1967a, b, 1972; Mackintosh 1971); painted turtles, *Chrysemys picta picta* (Pert and Gonzalez 1974); and terrestrial toads, *Bufo arenarum* (Muzio et al. 2006; Papini et al. 1995), but they do not show the same inverse relationship between reward magnitude and resistance to extinction. The same is not necessarily true for overtraining; overtraining extinction effects have been observed in mammals such as rats (Senkowski 1978; Theios and Brelsford 1964; Thombaugh 1967; Thombaugh and St. Jean 1972), but also in birds (Williams 1967) and in pond turtles (Ishida and Papini 1997; Pert and Gonzalez 1974), and in the octopus (Mackintosh and Mackintosh 1963).

## Parturition

Renu Bala

Department of Molecular and Human Genetics,  
Banaras Hindu University, Varanasi, India

## Definition

Parturition is the process of expelling a fully formed fetus from the uterus of the mother after the gestational period (38 +/– weeks in human females) is completed (Mijovic and Olson 1996).

## Parturition: A Complex Interplay of Various Physiological Processes

Parturition is a complex physiological process, which needs the precise interaction of various physiological events between maternal and fetal side. It's a millennial old concept that a fetus is a master of its own destiny and can sense when the placenta is no longer able to provide the sufficient oxygen and nutritional need of the fetus. In response to this stress, fetus activates a series of mechanisms to initiate labor and parturition (Mijovic and Olson 1996). Main physiological events involved in parturition are ripening and dilation of cervix, myometrium contractility, rupture of fetal membranes, separation of placenta, and uterine involution (Olson et al. 1995). Three main mediators such as steroid hormones, paracrine molecules, and inflammatory molecules control these events (Kamel 2010).

## Control of Parturition by Hormones, Paracrine, and Inflammatory Molecules

### Progesterone and Estrogen

Progesterone and estrogen are the main hormones involved in the maintenance of pregnancy as well as parturition. Levels of these hormones remain unaffected, but the sensitivity of the myometrium changes during various stages of pregnancy

via changes in their receptor expression. At the time of parturition, there is a functional withdrawal of progesterone by increasing the progesterone receptor A expression (myometrial contraction) as compared to progesterone receptor B (myometrial relaxation). Progesterone withdrawal also positively regulates the expression of estrogen receptor  $\alpha$  (ER- $\alpha$ ) at parturition, which increases myometrial sensitivity to estrogen (Pieber et al. 2001). Increased estrogen levels are also found to generate the action potential in myometrium by increasing the number, size, and permeability of gap junctions. Recent studies have also shown the genomic and non-genomic effects of various progesterone-responsive genes via nuclear factor kappa-B (NF-KB) promoter sites and 5 $\beta$ -dihydroprogesterone, respectively (Brown et al. 2004; Sheehan et al. 2005).

### Oxytocin and Vasopressin

Increased estrogen levels and expression of ER- $\alpha$  due to progesterone withdrawal stimulate the secretion of oxytocin and vasopressin, although the sensitivity of myometrium is lower to vasopressin than oxytocin (FUCHS and FUCHS 1984). The sources of intrauterine oxytocin are placenta, endometrium, and amnion. Oxytocin mRNA expression was found to increase in decidua with onset of labor at term (Mijovic and Olson 1996). The release of oxytocin is also stimulated by the diffusion of fetal hormones into the maternal circulation. Expression of oxytocin and vasopressin receptors in myometrium also increases before labor, which results in initiation of forceful contraction of myometrial smooth muscle cells (Akerlund 2004). When oxytocin binds to its receptors, phospholipase C gets activated, and there is an accumulation of intracellular calcium. Interaction of estrogen and oxytocin suggests the paracrine control of oxytocin and subsequent initial prostaglandin (PG) production in the intrauterine tissues such as decidua, chorion, and amnion (Fuchs et al. 1982).

### Prostaglandins

Prostaglandins have a role in cervical ripening and labor. The estrogen-mediated expression of

oxytocin receptors is enhanced by the PGs, which serves as a positive feedback in this cascade. The oxytocin gene expression is increased in hypothalamus due to stimulation by estrogen. In myometrial cells, oxytocin stimulates the hydrolysis of phosphatidylinositol resulting in the generation of second messenger inositol triphosphate (IP3) and diacylglycerol (DAG). Generation of IP3 activates a signal cascade leading to myometrial contraction, while cellular lipases act on DAG to release arachidonic acid, which is a substrate of PGs. Hydrolysis of phosphatidylinositol results in the release of intracellular calcium, which further helps in the mobilization of arachidonic acid. Oxytocin also helps in the production of endothelin-1, which helps in the calcium influx into myometrial cells resulting in uterine contractions (Mijovic and Olson 1996). Some reports have also suggested that during parturition, prostaglandins E2 (PGE2), PGF2- $\alpha$ , and thromboxane control uterine contractions via their specific receptors (Fischer et al. 2008).

Relaxin is another hormone present in the maternal decidua and chorion, but its exact role in human parturition is still under investigation. Few studies have shown its possible role in cervical ripening and rupture of membranes. It might have a paracrine effect and inhibit PGE2 production during pregnancy (Bernal et al. 1987).

Role of some other regulators of PG synthesis has also been postulated in labor. These molecules help in suppression of labor or uterine quiescence by inhibiting PG biosynthesis. Molecules such as phospholipase A<sub>2</sub> inhibitors, prostaglandin endoperoxide H synthase (PGHS), and nitric oxide have been found to inhibit the PG synthesis through various mechanisms (Wilson 1993; Garfield et al. 1995).

### Adrenocorticotropin, CRH, and Cortisol

Studies have shown that fetal adrenal and pituitary gland and the nervous system have a role in triggering the onset of labor. Fetal adrenal gland plays a role in parturition by synthesizing C<sub>19</sub> estrogen precursors and dehydroepiandrosterone (DHEA), as placenta is a major site of steroid

production and converts  $C_{19}$  estrogen precursors into estrogen and is closely related to the secretion of DHEAS from fetal adrenal gland (FUCHS and FUCHS 1984). In late gestation, mature fetal adrenal secretes cortisol resulting in increased levels of cortisol in fetal plasma. Onset of cortisol production is related to fetal adrenocorticotrophic hormone (ACTH), but studies have found that surge in cortisol occurs in spite of decreased ACTH levels. This was supported by the facts that not all anencephaly fetuses are born late. The role of fetal pituitary as well as placenta-derived factors such as corticotrophin-releasing hormone (CRH) and proopiomelanocortin-derived peptides (POMC) has been found in parturition (Riley and Challis 1991). Increased levels of CRH have been found in amniotic fluid and maternal circulation with advancing gestational age; however, there is a decrease in CRH-binding proteins. CRH synthesis is stimulated by prostaglandins, oxytocin, and stress (Kamel 2010).

Increased levels of glucocorticoids positively regulate CRH gene expression and mRNA levels. CRH also increases PG synthesis in myometrium, fetal membranes, and placenta, hence affecting the myometrial contractile response. CRH receptor expression also increases with gestational age and by two- to threefold at onset of labor (Speroff and Fritz 2005).

This suggests that estrogen, cortisol, CRH, prostaglandins, and oxytocin establish a positive feedback loop system and regulate the onset of labor as well as initiation of parturition.

### Inflammatory Molecules

It is a known fact that maternal-fetal tolerance is very necessary for the successful pregnancy. In addition to this, the role of inflammatory molecules and immune modulators in placenta and fetal membranes is well known in labor suggesting the contribution of regulated inflammatory reactions toward the initiation of labor or parturition (Keelan et al. 2003). These inflammatory molecules help in the release of PGs. Expression of various inflammatory molecules

such as IL-6, IL-8, and IL-1 $\beta$  was found to be increased at term labor. Various inflammatory changes such as increased levels of inflammatory cytokines, chemokines, and matrix metalloproteinases (MMPs) help in cervical ripening and myometrial activation during labor (Romero 1988). Expression of a highly conserved transcription factor nuclear factor kappa B (NF- $\kappa$ B) is associated with inflammatory responses. Expression of this gene is increased at the initiation of labor and starts a signal cascade leading to the expression of cyclooxygenase 2, contributing to functional withdrawal of progesterone, increased estrogen levels, and synthesis of PGs (Lindstrom and Bennett 2005). Levels of tumor necrosis factor-alpha (TNF- $\alpha$ ) and transforming growth factor-beta 1 (TGF- $\beta$ 1) were found to be elevated in amniotic fluid during labor (Hayashi et al. 2008). Some other studies have shown the role of cellular adhesion molecules {intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1) and endothelial leucocyte adhesion molecule-1 (ELAM-1)} in association with inflammatory reactions in labor (Steinborn et al. 1999).

Proteolytic enzymes such as plasminogen and MMPs play very significant role in extracellular matrix remodeling during pregnancy as well as at parturition. Increased expression of MMPs was observed in preterm birth (Tsatas et al. 1999). Higher level of inflammatory cytokines such as IL-8 was found to induce the infiltration of cervix by neutrophils, which promotes the release of proteinases helping in parturition (Winkler et al. 1999).

### Conclusion

The etiology of parturition is multifactorial. Various maternal and fetal hormones as well as inflammatory molecules function in a controlled way before the onset of labor subsequently leading to the initiation of labor followed by parturition. Synchronized interactions of these pathways lead to the cervical ripening,

myometrial activation and contractility, and rupture of membranes. Any disturbances in the balance or regulation of these mechanisms due to genetic, physiological, or environmental factors can affect the timely initiation of labor as well as parturition.

## Passerine Anatomy

### ► Passerine Morphology

## Passerine Cognition

Gisela Kaplan

School of Science and Technology, University of New England, Armidale, NSW, Australia

### Definitions and Features

It may seem counterintuitive to have to begin by talking about feet when the subject is cognition. However, the question of what passerines are has been determined by taxonomists, who classified birds with three unwebbed toes facing forward and one toe facing backward as passerines, or perching birds. With a few notable exceptions, most birds have four toes, but some have vestigial toes and effectively live with two or three toes; quite a few have two facing forward and two backward, but birds of the particular group known as “passerines” have three toes facing forward (called an anisodactyl foot), meant to promote perching.

Beak shape is not a good way to identify passerines. Beak shapes vary widely from short compact beaks as in finches to straight all-purpose beak as in flycatchers, sometimes massive beaks as in ravens to delicate and sometimes curved beaks of the honeyeaters.

To complicate matters, the labels “passerines” and “songbirds” have, at times, been used interchangeably, but this is not quite accurate. “Songbirds” (also called the true oscines) are defined by their vocal organ, the syrinx, and the number of muscles that operate this vocal organ, at least four pairs as shown in the second panel of Fig. 1. There are some passerines, such as the suboscines, which have three toes facing forward but not enough pairs of syringeal muscles (usually two pairs) to classify them as true songbirds. There are other birds with three toes facing forward, but they may have no syringeal muscles at all, and they are certainly not songbirds (such as tawny frogmouths). The distinctions are not altogether tidy because there are anatomical overlaps between the various groupings, but these are the currently accepted taxonomical distinction.

Apart from the toes, passerines have in common a quality that is of some considerable importance for the topic of cognition, namely, their immaturity at hatching (called altricial). When passerines hatch, they are helpless, often blind, featherless, and often not even able to stand on their feet and are thus completely dependent on adult care. This, for the parent bird (or both parents or even more than two adults), involves feeding and raising them, often well beyond the time when the offspring fledge.

While being altricial makes the newly hatched offspring much more vulnerable initially, biologically it has an advantage, namely, the opportunity for the offspring to develop as cognitively advanced a brain as possible. Indeed, the longer adults can care for their offspring, the greater the chances for optimal brain development. The brain is also a luxury. It is the most “expensive” organ in the body because, more than any other part of the body, it requires extensive high-quality nutrition and careful nurturing to develop fully. The interesting question is why some species, indeed families, have developed very large brains while others have not.

### How Many Are There

According to the most recent IOC World Bird List (Gill and Donsker 2017), there are 10,681 currently living species of birds (many more when subspecies are counted), and they are taxonomically subdivided by relatedness, their respective origin, and their categorization into superfamilies and eventually to species. Over half of them are passerines, thus an extremely large and diverse group of birds that have colonized every part of the globe.

As Fig. 2 shows, even the relevant part of the taxonomic bird tree is already quite complex just for tracing passerines. Panel I shows the ancient ancestors of songbirds; Panel II lists landbirds, among many others, and from those derive all perching birds. Passeriformes appear only in the third panel, and, of those, only the true songbirds have been included here, which are again subdivided into large groupings in Panel IV.

**Passerine Cognition, Fig. 1 Anatomical characteristics used in taxonomy for defining passerine birds. A, Ai:** The anisodactyl foot that gave perching birds their name. Three toes face forward and one backward. **Aii:** The toes are called digits and are numbered so that species with other foot configurations can be examined for their relative position. **B, Bi:** Showing the position of the syrinx in the body – the black circle indicates the location of the syrinx well inside the bird's chest. Songbirds also have a larynx, as marked, but it is of secondary importance in sound production. **Bii:** An enlargement of the outside of the syrinx – the tracheal and the lower bifurcation of the trachea into the two bronchial tubes is covered by muscles

organized in pairs to either side of the syrinx. Represented are the minimum number of pairs of muscles – four pairs – for a songbird. Many songbirds have five pairs, and some species may have as many as seven. The suboscines/Tyranni have at least two pairs, but many non-songbirds do not have any syringeal muscles. They may still produce sounds but to do so have to utilize the air sacs – as marked (Segment of Figure Bi adapted from Cornell Lab Animal free downloads, itself adapted from Rod Suthers, a former collaborator of the author of this entry, and Bii adaptation from a diagram of online site for Birds of South America II-Passerines by Ber van Perlo). For details of the syrinx proper and its functions, see Kaplan (2017)

P

An enlargement of Panel V highlights the superfamilies of Passerida, Corvoidea, and Meliphagoidea, but these groupings (and which species belong to them) certainly get revised quite regularly and change as we learn more about their deep relationships.

### Development of the Field of Avian (Passerine) Cognition

Cognition is a relatively new topic in science, first proposed for vertebrates in general in 1985 (Kummer and Goodall 1985). The idea of passerine cognition evolved slowly in the 1990s. The very idea of passerine cognition had been dismissed by most as anthropomorphizing, and,

for a long time, it was considered unscientific. The study of cognition in birds required an entirely new way of thinking, of asking new questions and conceiving of new research designs (and having the courage to think that this may be fruitful).

Some 20 years before Kummer and Goodall pleaded for some systematic investigations into vertebrate intelligence, guided by their work on chimpanzees, neuroscientists like Kuhlbeck (1967) had started systematizing comparative brain sizes. It is worth noting at the outset that, as early as the 1960s, birds were shown to have the largest brains relative to body size of any vertebrate (Table 1).

Hence, it has been known for a considerable time that birds have substantially larger brains relative to body size than mammals and

**Passerine Cognition, Fig. 2 Taxonomy of the passerines.** The passerines are thought to have begun to speciate only after the mass extinction 65 mya, whereas there is some evidence that some of its “sister” group developed much earlier. All songbirds and many other lineages of modern birds are now known to, or are suspected to, have evolved in East Gondwana, a kind of Noah’s arch for birds during the mass extinction events of 65 mya, which caused the extinction of dinosaurs and all other lineages of birds elsewhere in the world and of whose existence we have fossil evidence but no living descendants. The lineages that survived in East Gondwana (now Australia) are the ancient lineages on which all extant modern songbirds are based (Cracraft 2001). While passerines are just one of all orders of landbirds, they form the majority of all living birds. Note that the groups that are *not* passerines, even if they may share some features with passerines, are very diverse and form separate orders – these are the ratites such as ostriches, emus, and cassowaries and then the ducks, chickens, geese, swans, and other pond swimmers, such as moorhens and coots; grouse, quail, turkeys, and pheasants; seabirds such as albatrosses, shearwaters, skuas, and petrels and wading birds such as flamingos, herons, ibises, and egrets; swifts, swallows, and martins; shorebirds such as plovers; gulls and terns; and also raptors such as hawks, eagles, owls, and falcons and landbirds such as nightjars, kingfishers, hummingbirds, woodpeckers, barbets, and the large group of psittacine birds (cockatoos, parrots, lorikeets, and parakeets) that in new taxonomical assessments are considered a sister group of passerines (see [“Psittacine Cognition”](#) entry in this volume)

**Passerine Cognition, Table 1** Cuvier’s fraction for select vertebrates. Using simple ratios (Cuvier’s fraction E/S; E stands for brain weight and S for body weight),

| Species     | E/S ratio | Species      | E/S ratio |
|-------------|-----------|--------------|-----------|
| Small birds | 1/12      | Lion         | 1/550     |
| Human       | 1/40      | Elephant     | 1/560     |
| Mouse       | 1/40      | Horse        | 1/600     |
| Cat         | 1/100     | Shark        | 1/2496    |
| Dog         | 1/125     | Hippopotamus | 1/2789    |
| Frog        | 1/172     |              |           |

Kuhlenbeck (1967) noticed that these ratios did not necessarily match body weight. The larger the denominator, the less brain size had kept up with body size

vertebrates generally, foregrounding the topic of cognition and encouraging further exploration of brains and brain sizes of birds and vertebrates (see Fig. 3).

Such models have since been overtaken by more detailed assessments, but these first attempts threw some light on the evolution of the brain in animals generally, and the fascination with comparing brain sizes has never quite ceased since that time.

**Nonpasserine Avian Cognition**

Interestingly, passerine cognition was largely foregrounded and, at times, intercepted by cognitive studies of pigeons and chickens, belonging to two families that are not passerines. There are probably more papers written on pigeon cognition in the last five decades than on any other birds. Güntürkün and colleagues suggested in 2014 that pigeons ought to be used as an avian model species for cognition rather than any of the typical passerines – mostly zebra finches, but also canaries, sparrows, and, among the larger passerines, chiefly those that belong distantly or directly to the large group of Corvoidea and corvids.

The reasons for suggesting pigeons as a model species for avian cognition are persuasive. They live long, learn fast, and can easily be trained in captivity. They have a highly developed visual system and excel in complex visual discrimination tasks even as abstract as distinguishing between paintings such as Monet and Picasso solely on the basis of previous experience with different pictures of paintings by these artists. Pigeons are also better than humans in performing a discrimination task involving rotation and

volume changes of objects relative to other shapes. They are equally excellent in spatial ability and memory. Yet most of the experiments with pigeons were performed with captive, domesticated stock of rock pigeons (*Columba livia*) and were often not seen as suitable examples for telling us anything general that would be transferrable to passerine cognition, although this is of course highly debatable.

The study of chicken cognition is perhaps even more noteworthy because the group of fowl and their relatives (Galloanserae) are an ancient lineage separate from most modern birds (Neoaves; see Fig. 2, left panel) serving as a powerful reminder that implicit assumptions of *scala naturae* are incorrect. All songbirds first evolved in East Gondwana (now modern Australia), and fowl arose well before the last mass extinction of 65 million years ago, and they belong to the precocial species capable of independent feeding from day 2 post-hatching.

Chickens were mostly considered to be particularly lacking in anything approaching cognition. Yet a good deal of research has established that chickens can do astonishing things across a range of fields (auditory, visual, and social). For instance, a study of object permanence showed that even in their first week of life, domestic chicks are able to conceptualize the presence of an object that has disappeared from sight. If the chick is imprinted on a specific object, say a colored ball, it will follow the ball and stay close to it. If the ball is moved out of sight behind a screen for a little while, the chick will retain a concept of the ball and find it. When presented with two identical screens, it will approach and go

**Passerine Cognition, Fig. 3** Body weight versus brain weight – calculations in the 1960s. Symbols: black circles, mammals; black teardrops, primates including humans; black triangles, birds; hollow/crossed circles, amphibians, reptiles, and fishes (open triangle = budgerigar). The diagram above is adapted from an older summary of ratios between brain and body weight for all vertebrate groups (accessible on the Internet [www.neurophys.wisc.edu](http://www.neurophys.wisc.edu)) with the addition of some birds (cockatoos, macaws, and ravens) to reflect latest research insights. Upper bold

black line indicates mean values for trend lines in “higher” vertebrates – note that some passerines and psittacines, as well as dogs, great apes, humans, and cetaceans (dolphins and whales) have brain sizes well above the mean, while many nonpasserines and waterbirds are well below the mean (see entry for ostrich). Note that the black trend line for “lower vertebrates” (fishes, reptiles) is well below that of any birds or mammals. Based on Kuhlbeck (1967). (Adapted from the original Jerison, H. J. 1973. *Evolution of the brain and intelligence*. New York, Academic Press)

behind the screen around which it had seen the ball disappear. Children achieve this ability usually only between 7 and 9 years of age. Researchers arrived at the then radical conclusion that all animals that locomote independently and need to find their food by processes of identification and discrimination would have to be equipped with a minimal perceptual apparatus and a basic cognitive “software” to survive (Vallortigara in Rogers and Kaplan 2004). Astonishingly, they suggested that such software consists of rudimentary knowledge of physics (gravity, physical causality), mathematics (basic numeral understanding), geometry (spatial ability and landmarks), and psychology (distinguish

between friend and foe). Indeed, such traits have also been found in invertebrates. Honeybees (*Apis mellifera*), for instance, also have spatial memory and relational concepts; indeed, they have a basic numerical cognition that has now even been found in other insects.

### Passerine Cognition

When speaking of passerine cognition, one tends to refer to species that have actually been studied in detail. Most of our knowledge of passerine cognition derives from three groups but largely, although by no means exclusively, from Corvoidea (Table 2) and only a small number of families among those (a separate list of the corvids is provided in Table 3

**Passerine Cognition, Table 2** The superfamily of Corvoidea (within the passerine group of birds) consisting of 29 superfamilies. A family or superfamily marked “red” indicates that we have substantial amounts of published information about the cognitive abilities of a family or of some species within a superfamily. Blue indicates that we

have some, albeit generally sparse, information about species within this superfamily – unmarked are those superfamilies that may have very few if any studied examples of cognition, but this does not preclude that there are not some that contain species of which we have occasional observations or single incidents of cognitively advanced behavior

| Numbered | Species Names in Latin | Common names                                  |
|----------|------------------------|-----------------------------------------------|
| 1        | Paramythiidae:         | tit berrypecker and crested berrypeckers      |
| 2        | Psophodidae:           | whipbirds, jewel-babblers and quail-thrushes  |
| 3        | Platysteiridae:        | wattle-eyes and batiss                        |
| 4        | Tephrodornithidae:     | woodshrikes and allies                        |
| 5        | Prionopidae:           | helmetshrikes                                 |
| 6        | Malaconotidae:         | bush-shrikes                                  |
| 7        | Machaerirynchidae:     | boatbills                                     |
| 8        | Vangidae:              | vangas                                        |
| 9        | Pityriaseidae:         | Bornean bristlehead                           |

later) and just a smattering of species from other species, including bowerbirds. In toto, our knowledge base thus far may amount to possibly just 2–3% of extant passerine birds. But perhaps, at least in some superfamilies, the knowledge that we now have may be regarded as representative and significant of songbirds, certainly of some families. The very least that can be said is that never before in natural history or in science have we had so much data and evidence of passerine

cognition and never before has the idea of passerine cognition received so much in-depth research. Although, occasionally, there are some publications involving species belonging to Passerida or the Meliphagoidea, the Corvoidea are by far the most prominent group used in studies on passerine cognition (Table 1). Hence, what we know about passerine cognition tends to derive from a fraction of passerine birds but what a remarkable group of birds it is.

**Passerine Cognition, Table 3** Corvid species worldwide. Ravens, rooks, crows, and jackdaws have a firm. Presence on every continent, and usually with several species, excepting South America

---

**Africa/Middle East**

1. *Corvus albus* – pied crow (Central African coasts to Southern Africa)
2. *Corvus albicollis* – white-necked raven or Cape raven (Southern, Central, and Eastern Africa)
3. *Corvus capensis* – Cape crow or Cape rook (Eastern and Southern Africa)
4. *Corvus crassirostris* – thick-billed raven (Ethiopia)
5. *Corvus edithae* – Somali crow (eastern Africa)
6. *Corvus monedula* – jackdaw or western jackdaw (British Isles, Western Europe, Scandinavia, Northern Asia, Northern Africa)
7. *Corvus rhipidurus* – fan-tailed raven (Northeast Africa, Middle East)
8. *Corvus ruficollis* – brown-necked raven (North Africa, Arabian Peninsula, Afghanistan, Pakistan) – plus *Corvus ruficollis edithae*, Somali crow or dwarf raven (Northeast Africa)
9. *Corvus splendens* – house crow or Indian house crow (Indian subcontinent, Middle East, East Africa)

**Europe and Eurasian**

1. *Corvus corone* – carrion crow (Europe and Eastern Asia)
2. *Corvus frugilegus frugilegus* – rook
3. *Corvus monedula* – jackdaw or western jackdaw (British Isles and Western Europe, Scandinavia, Northern Asia, Northern Africa)
4. *Corvus corax* – common raven or northern raven (Holarctic regions of the Northern Hemisphere)
5. *Corvus cornix* – hooded crow (Northern and Eastern Europe and Northern Africa)
6. *Corvus corone* – carrion crow (Europe and Eastern Asia)
7. *Corvus dauuricus* – Daurian jackdaw (Eastern Europe to Eastern Japan, occasionally Scandinavia)

**Arctic Regions**

1. *Corvus caurinus* – northwestern crow (Olympic Peninsula to Southwest Alaska)
2. *Corvus cornix* – hooded crow (Northern and Eastern Europe and Northern Africa)
3. *Corvus corax* – common raven or northern raven (the Holarctic regions of the Northern Hemisphere)

**America (North)**

1. *Corvus brachyrhynchos* – American crow (United States, southern Canada, northern Mexico)
2. *Corvus corax* – common or northern raven (Holarctic regions of Northern Hemisphere)
3. *Corvus cryptoleucus* – Chihuahuan raven (Southwestern United States, Northwestern Mexico)
4. *Corvus ossifragus* – fish crow (Southwestern US coast)
5. *Corvus sinaloae* – Sinaloan crow (Pacific coast from Sonora to Colima)

**America (Central)**

1. *Corvus imparatus* – Tamaulipas crow (Gulf of Mexico coast)
2. *Corvus jamaicensis* – Jamaican crow (Jamaica)
3. *Corvus leucognaphalus* – white-necked crow (Haiti, Dominican Republic, Puerto Rico)
4. *Corvus nasicus* – Cuban crow (Cuba, Isla de la Juventud, Grand Caicos Island)
5. *Corvus palmarum* – palm crow (Cuba, Haiti, Dominican Republic)

**Pacific Ocean**

1. *Corvus hawaiiensis* (formerly *C. tropicus*) – Hawaiian crow (Hawaii)

**Asia**

1. *Corvus corone* – carrion crow (Europe and Eastern Asia)
  2. *Corvus enca* – slender-billed crow (Malaysia, Borneo, Indonesia)
  3. *Corvus florensis* – Flores crow (Flores Island)
  4. *Corvus typicus* – or Celebes pied crow (Sulawesi, Muna, Butung)
  5. *Corvus frugilegus* – rook
    - a. *Corvus frugilegus* (wide range across Europe and Mediterranean to Russia)
    - b. *Corvus frugilegus pastinator* – oriental rook (East Asia to Mongolia)
  6. *Corvus kubaryi* – Mariana crow (Guam, Rota)
-

|----------------------------------------------------------------------------------------------------------------------------------------|
| 7. <i>Corvus splendens</i> – house crow or Indian house crow (Indian subcontinent, Middle East, Eastern Africa)                        |
| 8. <i>Corvus macrorhynchos</i> – jungle crow (Eastern Asia, Himalayas, Philippines)                                                    |
| a. <i>Corvus macrorhynchos macrorhynchos</i> – large-billed crow                                                                       |
| b. <i>Corvus macrorhynchos levaillantii</i> – eastern jungle crow (India, Burma)                                                       |
| c. <i>Corvus macrorhynchos culminatus</i> – Indian jungle crow                                                                         |
| 9. <i>Corvus monedula</i> – jackdaw or western jackdaw (British Isles and Western Europe, Scandinavia, Northern Asia, Northern Africa) |
| 10. <i>Corvus torquatus</i> – collared crow (Eastern China, south into Vietnam)                                                        |
| <b>Australia/New Zealand/Oceania</b>                                                                                                   |
| 1. <i>Corvus coronoides</i> – Australian raven (Eastern and Southern Australia)                                                        |
| 2. <i>Corvus bennetti</i> – little crow (Australia)                                                                                    |
| 3. <i>Corvus mellori</i> – little raven (Southeastern Australia)                                                                       |
| 4. <i>Corvus tasmanicus</i> – forest raven or Tasmanian raven (Tasmania and adjacent south coast of Australia)                         |
| 5. <i>Corvus boreus</i> – relict raven (New South Wales, Australia)                                                                    |
| 6. <i>Corvus orru</i> – Torresian crow or Australian crow (Australia, New Guinea, and nearby islands)                                  |
| 7. <i>Corvus tristis</i> – gray crow or bare-faced crow (New Guinea and neighboring islands)                                           |
| 8. <i>Corvus fuscicapillus</i> – brown-headed crow (New Guinea)                                                                        |
| 9. <i>Corvus insularis</i> – Bismarck crow (Bismarck Archipelago, Papua New Guinea)                                                    |
| 10. <i>Corvus meeki</i> – Bougainville crow or Solomon Islands crow (Northern Solomon Islands)                                         |
| 11. <i>Corvus unicolor</i> – Banggai crow (Banggai Island)                                                                             |
| 12. <i>Corvus validus</i> – long-billed crow (Northern Moluccas)                                                                       |
| 13. <i>Corvus violaceus</i> – violet crow (Seram)                                                                                      |
| 14. <i>Corvus woodfordi</i> – white-billed crow or Solomon Islands crow (Southern Solomon Islands)                                     |
| 15. <i>Corvus moneduloides</i> – New Caledonian crow (New Caledonia, Loyalty Islands)                                                  |
| 16. <i>Corvus frugilegus</i> – rook (New Zealand)                                                                                      |

## Scientifically Acceptable Wish List of What Passerine Cognition Should Be

What is special about passerine cognition, if anything, needs to be carefully delineated from this basic “tool kit” of vertebrates and even some invertebrates generally. And one needs to bear in mind that some of the traits we once considered uniquely human are, in fact, not only shared by a few other mammals and birds but also by vertebrate and even invertebrate species in the distant evolutionary past.

Having said so, cognition, as applied to passerine cognition, is not a unitary term but involves many gradations – encompassing physical, core, and abstract knowledge as well as specific social knowledges. Scientists have carefully isolated areas of individual performances of passerines on very specific tasks.

Many researchers have made long catalogues of expectations that passerines would have to

meet before; they feel the term “cognition” could reasonably be applied to birds. Birds ought to show manifestations of complex memory (both making and maintaining memories, be this spatial, acoustic, seasonal, social), abilities for concept formation and categorization, remembering things that have gone out of sight (called object permanence), as well as being able to be a “time traveler”: that is, not only be able to remember the past but also plan for the future in the short term and possibly even the long term. Further, an individual ought to be able to judge what another may feel or think, which is called “inferring the state of another.” This may include behavior such as eye-gaze following (“I want to see what you see”), pointing, or responding to pointing (“I want to show you something”) in which expressions of intentionality and coordination should be apparent. Pointing and eye-gaze following involve not so much reading the behavior of another but interpreting what the other might

think it sees as important. Body movements, particularly when only showing pretended actions, can also serve as important markers that require an observer to interpret an intention. For instance, when a flight intention movement by a bird is not executed in order to set off on a flight itself but to encourage another bird to attempt flight, it is up to the second bird to read the intention as a signal for itself to take that action. It is the onlooker who has to make the important cognitive leap to perform an act that it is not the behavior that the demonstrator itself is actually doing but one that the demonstrator wants the observer to undertake.

Further, as others have identified, bird cognition should encompass abilities such as delay of gratification, reasoning, mirror self-recognition, and specific affiliative attitudes to others that show meaning is involved in the relationship, such as consoling a partner who may have lost a food item or, in a squabble, helping or defending a partner or group member in difficult situations, third-party interventions in serious fights (Güntürkün and Bugnyar 2016), or even more difficult emotions such as grieving, which perhaps might presuppose a concept of death or at least loss.

To complicate matters, debates on animal cognition, largely of primates, but at times including birds, have been framed in terms of theoretical debates on what is termed “theory of mind,” which not only includes attributing mental states to others but also an understanding that others can see, feel, and know which, in turn, is inextricably linked with a capacity for consciousness, insight, a concept of self, and such emotions as compassion (empathy) and even pride and shame as Charles Darwin had already outlined (Darwin 1904). While most researchers on passerine cognition have preferred not to get involved in debates on “theory of mind,” latest research results have shown that it may be increasingly difficult to avoid concluding that some passerine species may have a sense of consciousness and self.

While the bar was set very high as to what qualifies as “cognition” in birds, evidence of all of the above has been found in passerines.

## Evidence-Based Research Evaluating Cognition

The problem about regarding specific cognitive feats as a sign of cognitive complexity has remained and for good reason. Many species show one or the other trait that one might term “cognitively complex” but not all of the facets that together would make the organism seem so in all or most regards. As has been implied or argued by skeptics, avian brains are too small compared to, say, those of great apes or humans to be able to produce any noteworthy intelligent behavior. Even the most astounding documented feats of passerine behavior have, at times, been dismissed as examples of adaptations meant to indicate that not all complex behavior may not satisfy our understanding of cognition, and sometimes rightly so. The latter may well be true when a bird has shown a special skill, such as clever proto-tool use of opening walnuts in the great spotted woodpecker (*Dendrocopos major*), but shows few or no highly developed qualities in other facets of cognitive behavior. Of course, sometimes this impression of limited abilities is created when such findings are not followed up by new questions and experiments. For instance, as in the case of the Clark’s nutcracker (*Nucifraga columbiana*), it was always noted that its ability to hide and find some 30,000 pine nuts much later (recall of location of nuts exceeds 200 days) was extraordinary, but since Clark’s nutcrackers belong to scatter-hoarding taxa of relatively low phylogenetic diversity (i.e., various species of jays also scatter-hoard their food, and all belong to the corvid family), this was largely seen as an adaptive skill. Indeed, specialized skills may have been part of natural selection and encoded in the species’ genome: if Clark’s nutcrackers were unable to retrieve the nuts hidden in autumn and do so from under a blanket of snow in winter, they simply would not survive. Those who could not secure a safe food supply for the lean winter months might instead have been forced to migrate to wintering quarters with more easily accessible food sources. A different problem for birds, but just as potent, is the importance of remembering the ebb and flow of a food supply such as nectar. If

small honeyeaters should forget when and where a food source might be replenished, they would quickly deplete their own energy resources, already run at an exceptionally high metabolic rate, and die.

Hence, a good deal of seemingly cognitive behavior might indeed be the result of natural selection or thought of as being based on associative learning. Each case that is observed needs to be assessed rigorously, sifting through the possibilities of alternative explanations and, instead of speculating, opt for the explanation that is the most parsimonious and plausible in terms of its biological, behavioral, and environmental underpinnings.

### Risks and Pitfalls in Cognitive Research

The risks of over- or under-interpretation of behavior patterns that appear to be cognitive have always been great in this field. Historically, cognitive abilities tended to have been too readily dismissed or not even recognized as such, while, in current research, cognitive abilities at times may be at risk of being over-interpreted. Even now, however, cognitive abilities are often misused. A very telling example is the case of Clark's nutcracker. The assessment of finding nuts as an adaptive skill largely foreclosed further investigations for almost 30 years until Magnotti et al. (2015) tested Clark's nutcrackers in abstract concept learning in the laboratory, a task that capuchin and rhesus monkeys were known to have failed but human subjects were known to have solved. Superior learning by nutcrackers was shown to be due to their ability to learn an abstract concept, which can be determined only by transfer to novel stimuli. The researchers also pointed out, convincingly, that studies had previously failed to find evidence of such abstract cognition because of research designs that would have been unable to reveal it.

Another pitfall in the study of bird cognition is to treat an individual bird of a specific species as if it were representative of all individuals of the same species or even of the same order.

We now know that, as in humans, talents may be exceptional in one and not another individual

and circumstances may lead to the expression of certain skills while they cannot be demonstrated in others of the same species. The problem of variation has recently been addressed (Rowe and Healy 2014). Woodpecker finches, the first reported by Darwin and thus famous, are noted for their tool using, but, as research found, not all individuals of this species use tools, nor are non-using adults able to learn this skill by observation later in life. Tebbich et al. (2001) suggested that tool using in woodpecker finches may well be subject to being confined to a sensitive phase, just as is the case of vocal learning in some songbirds. This may demonstrate an important general point that not all clever skills may be evenly distributed among species or even within the same avian species or family group. There may also be learning opportunities that can be missed even if the potential for their expression exists, be this because of poor nutrition or a generally impoverished environment or because some catastrophic events undermined the time-tabling of receptiveness for certain intellectual or skill acquisitions – very much as we know is the case in humans.

Finally, we may at times still be haunted by assumptions about vertebrate cognition as an imaginary clear trajectory from lesser to greater cognitive ability coinciding with the size of brain/body ratio and an evolutionary timetable (a view that the brain/body ratio tables enforced rather than dispelled – see Fig. 3 above). And the order was simple: invertebrates as the lowest creatures, then fish, followed by amphibians and reptiles, then birds, and finally mammals and, at the apex, nonhuman primates and humans. This assumption is as old as Aristotle and referred to as *scala naturae*. However, as researchers on fish have discovered, many of the debating points about cognition discussed in primates could be discussed and found in fish (see chapter in Rogers and Kaplan 2004). Work on bees has more recently shown that bees form memories, and another invertebrate, the octopus, has problem-solving abilities.

The point made here is twofold: during the process of evolution, traits can be gained and lost and regained again. The second point is that

environmental niches impose their own challenges, risks, and prerequisites and survival in any of them will foster physical adaptations, skills, and problem-solving abilities that fit such challenges best – no more and no less. Even the bird's ability of flight is lost when environmental circumstances make it pointless to possess flying ability.

## Key Areas of Interest in Passerine Cognition

Research on passerine cognition has concentrated on three entirely different areas: (1) song development and/or vocal learning, (2) brain and brain functions, and (3) behavioral studies revealing cognition.

These three areas have increasingly begun to overlap and grow together. This third cluster of research interests (cognition), relatively later on the scene than the previous two, investigated aspects of bird behavior that fell into a very varied basket of “cognitive behavior” – starting perhaps with tool using, innovation, and insightful problem-solving and a raft of other special abilities extending to mental time travel (ability to remember past events and conceive of events that have not yet taken place) and awareness of others and many more abstract cognitive abilities.

In the following sections, the directions and details of interest and extraordinary findings in passerine cognition are briefly outlined. From the relatively few species studied, it is clear that those species researchers have studied in great detail have astonished the researchers and the world with a wide range of abilities and surprising characteristics that were all once, and often until very recently, thought to be the province of humans as the only species, or one of the few (such as great apes), to show advanced cognitive abilities and behavior.

### Song and Vocal Learning

The most outstanding feature of most passerines is that they can sing. The study of passerine cognition received significant impetus and was also foregrounded by extensive work on birdsong

and birdsong acquisition generally and by the neuroscience of birdsong that dealt specifically with forebrain activity required for vocal learning and thus with significant aspects of passerine cognition. By far the most favored species in neuroscience for birdsong learning and memory have been zebra finches, canaries, and a smattering of others, while those more interested in the social aspects of vocal behavior of passerines have concentrated on well-known songbirds such as starlings, nightingales, mockingbirds, lyrebirds, and Australian magpies, and generally a wide range of songbirds have been studied in these regards.

Many of the songbirds such as mockingbirds, drongos, orioles, starlings, jays, bowerbirds, pipits, bush larks, warblers, towhees, Australian magpies, brown thornbills, and brown thrashers, to name just a few, can even mimic other species. The latter ability was incontrovertible proof that mimicry had to be learned since it was not accessible from an inherited template but had to be acquired during the lifetime of an individual. Very few other orders and species can learn vocalizations let alone mimic other species. Vocal learning is thus a rare quality in the animal kingdom that has so far only been discovered in very disparate groups such as cetaceans (e.g., whales/dolphins), in elephants, in some hummingbirds, in psittacine (parrot/cockatoo) species, and first and foremost in songbirds and humans. In songbirds, parrots, and humans, such capacity for learning sounds has often developed to highly sophisticated levels.

Most of the processes associated with song learning required discovery of an enabling neural network for hearing sounds, remembering them, and then reproducing what was heard. Further, song production and variations, indeed any vocal utterances, raised the question of memory as to how and what was stored and could be recalled when needed and how learning occurred so that vocal signals were used appropriately and in the correct context (Fig. 4).

A large cluster of singers belong to species in which song is exclusive to males that sing to attract a female in competition with other males. They tend to be migratory and, for reasons of climate and rapid seasonal changes, have little

**Passerine Cognition, Fig. 4** Schematic (simplified) representation of the anatomy of the song system. The crosshatched nuclei, HVC, RA (robust nucleus of the arcopallium), and nXIIts (the tracheosyringeal portion of the hypoglossal nucleus), form part of the descending motor pathway for song. Black: The nuclei of Area X, DLM (medial subdivision of the dorsolateral nucleus of the anterior thalamus), and LMAN (lateral magnocellular nucleus of the anterior nidopallium, shown in solid black) form a pathway indirectly connecting HVC to the RA and play a special role during song learning. The primary sources of auditory input to the song system are the field L complex (large area (light gray) subdivided into L1, L2, and L3) and its projections to the shelf underlying HVC (stippled areas)

time to reproduce and rear young that are then strong enough to also leave their nesting grounds and fly to wintering grounds, often thousands of kilometers away. Many of these males with elaborate song (and sometimes pronounced and colorful plumage) tend not to co-rear their young. Their song may be long or short and often may not vary much from year to year, and, however dazzling the performance may be at the time of the breeding season, the actual contents may be modest, saying no more than that the individual singer has stamina and is healthy. Beyond this capacity to have learned a song, it is no indication of any other cognitive skills.

Another cluster of species, sometimes also exclusively male, uses song to announce territorial ownership, and quite often such song may not need to be very elaborate.

In many songbirds, as has recently been researched in detail (Hall and Langmore 2017), female song is also ancestral and can be found in

**Passerine Cognition, Fig. 5** The zebra finch song control system is used as a model case. The male zebra finch is probably the most intensely studied songbird and has yielded the most detailed data on song learning. The zebra finch learns song mostly and best from a male tutor but needs to have completed the learning phase during “a sensitive period,” and this process is usually completed by 90 days post-hatching, when song crystallizes

hundreds of passerine species, such as in most species of the shrike family, in all Artamidae (Australian magpies, butcher-birds, currawongs), orioles, drongos, various corvids, cuckoo shrikes, and many more songbirds across different families of passerine birds such as wrens, gerygones, and thornbills (Odom et al. 2013). Many of these have not been studied in detail or not at all neither has the function of song (not used in a reproductive context) been examined nor song learning been investigated in the light of cognitive power than does male-song learning and practice for which the functions are well-known and studied.

Very careful consideration has been given to male-only (sexually dimorphic) song used during the breeding season. Model species usually chosen are zebra finches (*Taeniopygia guttata*) and less so canaries and sparrows. In the zebra finch (Fig. 5), song is learned from a male tutor, usually the father, and the zebra finch juvenile has only limited time to acquire the song (called the “sensitive period”), and then the song “crystallizes,” meaning that it takes its final form at the end of the

sensitive period. The zebra finch model of song acquisition is very useful because of its applicability to quite a number of songbirds. At least research for this group was able to show beyond doubt that birds need the forebrain in order to learn, need a memory to store what has been learned, and retrieve it in contexts that are meaningful to others.

Yet it would be wrong to assume that acquiring a mate is the major or even the only function of song. The zebra finch song learning model already breaks down in contexts of song being used to guard territory. Quite typically, in pairs that settle in one specific plot and are in the position to hold their plot over some time, even years, it has been observed that part of their song may converge with that of neighbors. The neighborhood is thus defined by some shared song components that arise dynamically depending on the composition of various plot holders. Clearly, birds cannot learn in advance who they might encounter in the future or where they can secure a territory, meaning that the brain has to remain flexible enough to be able to learn some new sounds.

Finally, there is also a substantial group of lifelong learners that retain the ability to learn new patterns of vocal behavior and even a range of nonvocal cognitive tasks. This flexibility and ongoing learning ability (open-ended learning which is an example of “brain plasticity”) are characteristic of the group that appears to have the greatest potential for complex cognitive abilities; at least one would be led to believe so based on the findings in studies of lifelong learners.

In some cases, as was discovered, vocal communication is refined to a point where individual signals might even be regarded as the beginnings of a lexicon, i.e., the beginnings of what we call “language”: specific sounds that symbolically get earmarked to refer to a specific object or message and are voiced only in the presence of conspecifics. This, in vertebrates generally, is referred to as “referential signaling.” Chickens also use referential signals, so this ability may be more widespread among birds than we currently know, and not just limited to songbirds or passerines in general, or it may be one of the traits gained and lost

over evolutionary time. It was rightly assumed that such avian species had to possess the neural apparatus to process information about referential signals and retain a memory of what had been communicated in a way that humans are known to do.

Song learning in birds recently held a further surprise. In 2008, Prather and colleagues showed that songbirds have mirror neurons that promote learning and long-lasting memory formations in a very special way. A bird can listen to a song and form a memory of it as if it had sung and practiced it itself.

The most convincing aspect of these findings is that these neurons belong to a population of neurons that is not replaced, as other neurons in the song system are (Nottebohm 1980), but is stable across song development. It is this stability in neurons that enables the juvenile to improve its song as the memory trace of the correct version remains intact and can be accessed.

Identifying mirror neurons in birds was such an important discovery because it explained for the first time how songbirds, such as the Australian magpie (Fig. 6), can learn their song without exposure to a tutor. It also explains why songbirds such as Australian magpies can be seen practicing on their own and yet improve the quality of song or mimicry of sounds they have heard. Indeed, magpies (*G. tibicen*) need to hear a particular sequence just once and, after a lag time of about 24–48 h, can produce a good rendition of the complete sound sequence. The same ability has been demonstrated in starlings and mockingbirds and quite a few other species. Even more astonishingly, there is documented evidence that Australian magpies, when trying to mimic a difficult sound sequence (such as level of kHz, speed, etc.), will continue practicing without any further exposure to the original sound sequence while measurably improving the accuracy of its mimicked performance only heard once in the real world. Presumably, this can only happen if there is a memory template of the original against which the singer can practice. Unless we discover other mechanisms, it seems that the mirror neurons are of substantial importance for memory in the passerine brain.

**Passerine Cognition, Fig. 6 The Australian magpie as an alternative model.** The magpie is a representative species at the other end of the spectrum of birdsong learning (the dominant model is the zebra finch – see Fig. 5). Magpies improvise song, have a substantial repertoire, and belong to the group of lifelong learners. Song is never fixed. Magpies, one of the most versatile and melodious songbirds of Australia, are also distinguished from zebra finches in that both males and females sing alike. The bird is not only an excellent mimic but shows cognitive behavior on a par with corvids. Unlike many corvids that are persecuted and culled as vermin, magpies suffer no neophobia and often form lifelong friendships with households in suburban and rural areas. They are strictly territorial and often raise their offspring cooperatively. The magpie is so far only one of two species in which pointing behavior was demonstrated (*Corvus corax* is the other species)

### The Brain

One notable piece of evidence of evolutionary distance was that birds, but not mammals, lack the neocortex, the convoluted area of the brain that was believed to be a prerequisite for complex thought and memory (see Fig. 7). Indeed, it was believed for a long time that meaningful vocal communication was unique to humans. These turned out to be an incorrect assumption. It was thus a major breakthrough to discover that songbirds, despite the evolutionary distance from humans, had the mechanisms to learn

vocalizations (rather than produce sound merely instinctively) and had to rely on forebrain abilities as humans do.

This insight propelled science further to consider what similarities there might be between human and bird brains, admittedly by a process of convergent evolution. In 2004, an international team came together forming the “Avian Brain Nomenclature Forum” to rename the different regions of the avian brain, largely using the small Australian songbird, the zebra finch, as the model species for all passerines. More daringly, in a question which would have been dismissed as fantasy a century earlier, it was asked what can be learned from a bird brain in terms of mechanisms and dynamics of vocal development and retention of sounds that might inform understanding of these processes in humans. All other inquiries into the capacities of the passerine bird brain followed on from the initial interest in trying to understand the development and mechanisms of birdsong.

The second large area of ongoing and intense research is concerned with the perceptual abilities of birds, asking what they see and hear and, importantly, how they navigate in their environment and remember food locations (spatial orientation and spatial memory), also creating a need to look very closely at areas of the brain not directly associated with song learning.

### Brain Weight as a Ratio of Body Weight Versus Neuron and Synaptic Density

In 2009, researchers (Overington et al. 2009) looked for species with documented instances of innovative feeding (be this consuming novel food or using tools to access food) and found examples of this in 800 species worldwide. According to their findings, they argued that it is the brain size (in relation to body size) that made it possible for animals to produce novel behavior patterns. This concerned not only individuals and individual species but also families. Interestingly, they also found that one might predict from behavior alone whether the species was large-brained or not and do so by looking at the diversity of innovations performed and not just the total number of innovations.

**Passerine Cognition, Fig. 7** Rostro-caudal (side-way) view of magpie brain (Panel A) and human brain (Panel B). The human brain is about 150 mm long and has a volume of about 1450 cm<sup>3</sup>. The magpie brain (using the same measures) is about 35 mm long and has a volume of 4.65 cm<sup>3</sup>. The scale bar (gray/stippled) indicates the

relative length of the magpie brain when compared to the human brain. As already indicated, brain size by itself is no indication of relative neuron density. Note that the surface area in all birds is smooth and in the human brain is entirely convoluted. Even so the basic architecture of the brain is similar both in humans and birds

The problem with this approach to passerine cognition is that the argument rests its case on brain volume. Yet brain size may not by itself be able to account for the vast breadth of variations in cognition in passerine birds. Thus, ratios were introduced, relating brain volume with body size. The next logical step was to look at the distribution of neurons and the number and density of neurons.

There are several pitfalls in this reliance on brain/weight ratios alone because it assumes invariability in the architecture and function of the brain and of neurons. One biological fact is that different parts of the brain may have different size allocations according to need, meaning that size can vary from one season to the next or over a lifetime even in one individual. The part of the brain known as the hippocampus, for instance, particularly noted for the ability to form and retrieve spatial memories, is a case in point. It has been shown that in species that store and hide their food, the hippocampus is larger than in those, even in closely related species, that do not scatter-hoarded food. Or, more dramatically, the hippocampus may even shrink in a food-storing bird that stops storing food for a while. The size of the hippocampus varies with seasons and can even vary from one individual to the next, depending on the opportunity to store food, growing larger when such opportunities exist (Krebs et al. 1996). Likewise, the number of neurons in the forebrain

(called the pallium in the avian brain, see Fig. 7) may not be the decisive trigger for cognitive behavior. This important task depends also on the activation or suppression of the links between neurons (synapses), as well as on the number of synapses per neuron and, especially, on the number of synapses that will actually fire in certain circumstances. It is this trigger that will result in action (interneuronal spiking) and, as importantly, may also inhibit actions. It has recently been found that those neuronal synapses that inhibit neural activity may well be equally important for song learning as are synapses that stimulate neural activity. In zebra finch song learning, inhibition works to protect song elements that have already been learned.

#### Neuron Counts

A final point concerns the neuron counts: there are vast differences in neuron densities between different brains. Recent research has struggled with the idea that it was not the brain size or the brain-to-body weight ratio that is important but that one needed to look in detail at the neuron density in the brain generally, and in the forebrain specifically, in order to arrive at some biological basis for the differences in cognitive abilities among birds and other vertebrates. A paper of 2016 that was quoted all over the world bore the title: “Birds have primate like numbers of neurons in the

forebrain” (Olkowicza et al. 2016). These authors argued that it was not just a matter of volume but a matter of the density of neurons and their location in the forebrain that determined how cognitively enabled and innovative a bird might be. Expressed differently, the researchers had wondered how birds, in this case ravens, were able to do complex tasks on a par with primates when their brains overall are so much smaller, and they concluded that the bird’s neuronal density is much higher than that in primate brains.

Another possibly new and yet untested interpretation, that fits well with the idea of natural constraints on basic brain design, is that biology imposes constraints on minimum and maximum numbers of neurons possible for vertebrate organisms as Fig. 8 may illustrate. Thus, variability remains within certain limits, no matter how small or large the overall body size.

Figure 8 demonstrates a possibly crucial principle that was already shown by Kuhlenbeck across vertebrates (see Table 1 above) and here is demonstrated and consistent also within the class of avian species. Looking at the trend line (stippled line in orange), there seems to be a trend for neuronal density to *increase* as body and overall brain size *decreases*. The sample of species is not large enough to confirm a significant trend. Nevertheless, the current data show at least that very small birds pack in an enormously large number of neurons into a very small space, while large birds have lower neuron density. The number of neurons has remained very similar across species with wide-ranging body weights. Similarly, when primates are compared with songbirds, if this principle is correct, then it ought not to surprise that, despite large differences in body size, there is a similar neuron density in both

**Passerine Cognition, Fig. 8** Ten songbird species – body weight versus neuron density. Blue bar signifies body weight of songbird – actual average body weight of the songbird next to blue bar in grams (e.g., great tit, 17.2); orange bar indicates the ratio of neurons to brain mass, showing that the largest bird, the raven (bottom line), has the lowest neuron density and one of the very smallest

birds, the zebra finch, has the *highest* in this sample. The insert (Adapted from Olkowicza et al. 2016, part of their Fig. 3a, plotted as a log scale) addresses specifically the ratios of forebrain neuron densities (rather than overall neuronal density) and finds that they are specifically high in songbird (green for songbirds) when compared to primates

groups. Expressed differently, biologically a vertebrate brain may require a minimum number of neurons to function efficiently, while beyond a certain maximum number of neurons, it would be wasteful to add more neurons even if the body size increased.

Finally, structure may not always coincide with function, meaning the former may just express a potential of the latter. It is worth remembering that the brain is a dynamic system, capable of responding to environmental factors that may change allocation of neurons or impair or enhance function as the case may be. For example, poor nutrition or high levels of stress during development may contribute to reduced brain growth overall, even to aberrations, or at least to severe limitations of its genetic optimal expression.

#### Laterality and Cognition

Passerines, indeed most avian species, have their eyes positioned laterally (on each side of the head) so that the optic axes are not parallel, as they are in some nightjars, all owls, cats, primates, and humans, but directed outward. The visual field of passerine birds is thus largely monocular with good acuity sideways and with only a small binocular visual field for viewing close objects. To complicate matters further, information from the right eye is received by the left hemisphere of the brain and the information from the left eye in the right hemisphere. It has been shown in the European starling (*Sturnus vulgaris*) that there is an uneven distribution of photoreceptors in the retinas of the left and right eye. Hence, each eye may send quite different inputs to their respective hemispheres. The left-right separation could potentially carry disadvantages or at least constitute unnecessary duplications. Instead, the avian brain, similar to that of other vertebrates, has turned laterality of the brain into a major advantage for survival and general cognitive power – if the left and right hemisphere can do slightly or very different things and/or modify the responses of one side with the inhibition by the other (such as curtailing fear when action is needed), then the cognitive power of and control over the organism's decision-making would be substantially enhanced.

So far, we know of the brain lateralization in passerines in only a few species, such as zebra finches, marsh tits (*Parus palustris*), European starlings, American tree sparrows (*Spizella arborea*), New Caledonia crows (*Corvus moneduloides*), and Australian Magpies. Extensive studies by Rogers (2012) over some years found that in the avian brain, the right hemisphere (use of left eye) is specialized to notice details and respond to novel stimuli. It controls fear, escape, aggression, and sexual behavior and may also be specialized for social behavior, while the left hemisphere (use of right eye) is specialized for categorizing stimuli and hence for learning to distinguish one class of objects from another. Rogers demonstrated this in seed-eating birds, by scattering grain among pebbles. The pebbles looked very similar in size and color to grains: when using both eyes (binocular vision), the birds have no problems in distinguishing food grains from pebbles. Their performance remains the same when using only their right eye but not if they can use only their left eye. When using only the left eye – right hemisphere – birds fail to discriminate between pebbles and seeds.

Research has also shown that birds with laterally placed eyes show responses to predators and conspecific on their left side and to prey on their right side. This has been demonstrated in the Australian magpie showing a clear left-eye preference (right hemisphere) for scanning overhead for an eagle (Kaplan 2017) confirming results also in other avian species that the right hemisphere has broad attention and can attend to unexpected stimuli such as a predator, whereas the left hemisphere may focus on specific tasks. In songbirds, courtship displays are activated by the left hemisphere, controlling right hemisphere-instigated copulation, as can be observed in male zebra finches, for example, that fixate the female with their right eye (left hemisphere) while they perform copulation displays. Overall, given that specific aspects of making sense of the world are controlled by different sides of the brain, lateralization of the brain enhances cognitive capacity and efficiency by retaining the possibility of integrating the information received and the varying capabilities of each side to responding to a

multitude of stimuli. Being able to attend to two tasks at the same time when each task is controlled by a different hemisphere also has clear survival value (i.e., being able to pay attention to ground foraging while remaining vigilant to a predator overhead).

### Ravens and Crows: A Special Case

Before turning to a discussion on specific kinds of the expression of cognitive behavior, ravens and crows need a separate mention because they have taken center stage in research on passerine (oscine) cognition. Indeed, highly productive and substantial research has documented a range of cognitive abilities in corvids that even just 10 years ago would have seemed highly improbable fantasy and are still regarded as exceptional among birds and vertebrates generally. Corvids have emerged as an impressively versatile and cognitively complex group of passerine birds.

Just as zebra finches became the model subject for research on birdsong, corvids have taken center stage in passerine cognition research, and, in both cases, this has had very positive and some unintended negative repercussions.

Ravens and crows as a group (the Corvidae) are useful subjects partly because of their cosmopolitan presence in the world and their easy access. Their Gondwanan origin notwithstanding,

corvids have spread all around the world, consisting of a core group of corvids, which includes crows, rooks, jackdaws, and ravens, making up more than a third of all corvid species worldwide (see Table 3 listing core corvids by distribution below). The core group of “corvus” tends to be rather similar in appearance (Fig. 9). Most of the corvus group are large birds, indeed among the largest songbirds, have strong all-purpose beaks, and have black plumage (some species have some gray plumage as well), and there are generally few, if any, discernible differences between the sexes. When all species are included, the entire family of the Corvidae (e.g., the jays, magpies, tree pies, choughs, and nutcrackers), the number of species rises substantially (to about 120). Especially among the large group of jays, one finds species that are smaller than ravens and crows and also quite often rather colorful (as the Eurasian jay) often bearing no outward resemblance to corvids.

Common ravens and rooks are most often used in cognitive research, while a number of species of jays and nutcrackers have been used in research on episodic memory (recall of past events and accurate retrieval of food taking into account not only where it was stored but also when it was stored) because they scatter-store their food, and hence they are natural choices for study of

**Passerine Cognition, Fig. 9** Cosmopolitan ravens and crows. Left: A common raven (*Corvus corax*) found across much of the northern hemisphere. Right: A Torresian crow (*Corvus orru*) of subtropical Australia and neighboring

islands – slightly smaller beak than *Corvus corax* but similar in size and sleek black feathers but white/light blue iris as against the dark brown eyes of the common raven. Jackdaws have largely dark gray plumage

memory of what and where something was stored and when it was retrieved.

Although song is not one of the most noted abilities in corvids, complex vocal and social communication is. Latest research has identified that Torresian crows use over 200 vocalizations in communication with conspecifics (McCaig et al. 2015). What raven research on cognition is most noted for is the degree of insight and stunning subtleties of social behavior (see entry ► [“Social Behavior”](#)). If one looked for an example of the relationship between cognition and social life, it is amply and well demonstrated in corvids. Ravens distinguish individuals, and it is now even known that ravens will remember individual human faces that have proven to be dangerous.

However, there are several criteria that ought to caution us against drawing the conclusion, as has quite often happened in recent years, that corvids are therefore the smartest birds of all birds and apparently of all passerines. Given our limited state of knowledge overall about individual species and even families, to draw such conclusions might well be premature; and even with the body of evidence that we already have of other birds, this has already been found to be factually incorrect.

There are reasons why corvids have become so prominent in passerine cognition research. First, there is a practical reason. This simply relates to the number of years and the number of researchers who, often over decades now, have studied specific species of corvids in great detail and have developed facilities for the long-term care and housing. Centers of research in Europe, especially in Austria and England, as well as in the United States and New Caledonia, have dedicated excellent facilities or sites to their study. In some cases, birds spend their long lives with well-known human researchers (reducing fear, increasing familiarity) leading to more representative research outcomes.

Increased knowledge derived from studying their behavior has also led to increasingly sophisticated research questions and some brilliant research designs, such as studying behavior that was once considered unobservable (Correia et al. 2007; Bugnyar et al. 2016). The same is true of

Australian magpies whose cognitive behavior has now been studied for 25 years (Kaplan 2019). Hence, the fact that such species have revealed so many astounding abilities and traits may partly be a consequence of the consistency of research making the formulation of hypotheses more sure-footed on a background of reliable and known data.

By contrast, we may possess no more than one or two studies and often quite fleeting observations of many other passerine species and often none at all for possibly thousands of others. If, on the other hand, the same depth of results could be achieved in other passerine birds, at least derived from a few families other than corvids, it is more likely than not that more or new aspects of cognition could be found in such species as well. Comparative work might also lead to questions about phylogeny, the evolution of high levels of cognitive abilities, and how these relate to environmental niches, to family structure, to life histories, to broad social rules, and even to levels of cooperative behavior. These relationships may be important, and some syntheses have been proposed, but we need more studies to be certain as to what they are. One might well also discover that some sophisticated cognitive abilities may be more widespread than can currently be claimed.

Finally, the sheer body of evidence of corvid abilities has also led to statements such as that corvids are the only truly “intelligent” birds. This is factually incorrect. In some instances, it reflects a problem of international communication. Particularly with respect to studies conducted in Africa, South America, or Australia, some findings of avian cognition and extraordinary findings have gone unnoticed or might have been ignored, and some may remain almost entirely unknown, a geopolitical bias that is being increasingly seen as needing to be more fully addressed for the sake of scientific accuracy.

The claim, repeatedly made, that ravens are the only non-hominid animals that have demonstrated planning beyond the current moment, like great apes, is factually incorrect. Anticipatory planning regardless of motivational state had been researched in western scrub jays some years ago (Correia et al. 2007). Negotiations for future

events and roster systems in cooperatively breeding passerines have been studied in other songbirds not even distantly related to ravens. For instance, there has been a fascinating study investigating negotiations in African pied babblers, *Turdoides bicolor*. Indeed, the cooperatively breeding pied babblers have been studied in some considerable detail including demonstrating teaching skills to offspring and routine kleptoparasitism. One particular study of a wild population of pied babblers in South Africa investigated in-group role divisions (Bell et al. 2010). These babblers developed sophisticated levels of negotiations about future sentinel and feeding duties. Indeed, Bell et al. (2010) showed convincingly that individual pied babblers were capable of making anticipatory adjustments to personal investment of helping based on information about the likely future contributions of collaborators. This reciprocity principle (“I will do x if you will do y”) is surely among the most cognitively complex inter-individual interactions so far recorded.

Hence, while the corvid family has become a model family for study of cognition in passerines, it does not follow that this should foreclose research on very different passerines. In doing so, we could well overlook important principles of the evolution of cognition in birds. This, of course, does not invalidate anything we now know about corvid cognition, but it certainly makes it a more urgent task to see how other large families of passerines have fared in their cognitive abilities.

## Studying Behavior: Passerine Cognition as a Graded System

Cognition in passerines has now been studied for long enough to derive the view that passerines are not simply guided by instinct but, to varying degrees, are equipped with the ability to learn, to remember, to solve problems, to innovate, and to communicate in ways that presuppose active decision-making and sometimes innovation and complex problem-solving (ten Cate and Healy 2017). Having said so, however, there are some

skills that are called adaptive because every member of the species can perform them and do so from one generation to another without any evidence of learning. Hence, some of the clever things we might see birds doing have become part of the repertoire of the species suiting their ecological niche.

Part of a basic tool kit also seems to be some basic knowledge that, surprisingly, has been described in terms of disciplines of mathematics (numeracy), geometry (spatial ability), physics (understanding gravity), and even psychology (correctly interpreting the behavior of others or understanding that objects and living things remain complete when half their body may be hidden, called object permanence). It was up to research efforts to establish whether some of the abilities in this basic “tool kit” required active reasoning and to understand whether they were based on some understanding of causality (Vallortigara et al. 2010).

Some cognitive processes are domain-specific, and these are usually referred to as modules. All studies on animal cognition in general have tended to be modular to some extent, i.e., observed skills in one domain followed by testing such particular abilities. Inevitably, research had to concentrate on very specific questions and slowly assemble a picture of the birds’ cognitive world. Some investigations started with natural behavior associated with food acquisition and reproduction, two of the most basic abilities for survival in an individual and the species. Some aspects of spatial abilities, tool use, on causal relationships and now even on matters such as nest and bower building have been explored. The latter have been called physical cognition.

## Nest Building

There are gradations in skill and complexity in nest building. Some very specific examples of nest building may in fact be well explained under the rubric of tool use, innovation, and even creativity.

Building nests in trees was in itself perhaps one of the most important innovations in passerine evolution. Passerines, together with birds of prey, are the main groups of birds that

overwhelmingly build nests in elevated positions, often requiring quite complex processes of tie-downs, observing wind direction, and other structural particulars. Water- and shorebirds, many families other than passerines, and the entire clade of fowl either build ground nests or may hollow out a depression to make a nest, or they may just nest half-hidden in grass or on bare sand or rock. Psittacine species and some other families, such as owls and kingfishers and, unusually, Indian mynas, breed in tree hollows, and yet some others may prefer to find nests others have built. Passerines are the ones consistently adept at using a variety of materials (sticks, spider webs, mud, down feathers, and even manufactured materials such as wires, plastic, clothes, fly-screen wires, and more). They often combine very different materials to satisfy the conditions needed for nestling protection from the elements, and they often camouflage the nest site by the additions of local/natural materials. Recent experimental work has shown that zebra finches are able to learn about nest building from not only their own experiences but also socially, from watching other familiar (but not unfamiliar) birds build (Guillette et al. 2016).

In the northwestern part of Europe, over a 30-year period, astonishingly, in just this one region, there is evidence of as many as 176 nesting innovations spread over a number of passerine species. There have been reports of similar frequency of nesting innovations (be this in location, tie-down, or nest materials used) in Australia (Kaplan 2015), and it would not be far-fetched to proclaim that birds, as architects, have found means of improving their lives or exploited new opportunities. No doubt, innovations, by their very nature, have to rely on forebrain activity, and, if it is a good invention, it can also be copied by others acquiring the skills needed to construct something new. Overington et al. (2009) drew the conclusion from their study that technical innovations drive the relationship between innovativeness and residual brain size.

### **Bower Building**

A peculiar habit of one group of passerines, the bowerbirds, is that all of them build bowers, some

more elaborate than others. Regent bowerbirds build relatively simple structures but dance in addition for their displays, while other species build more elaborate bowers that may involve using “paint” and brushing on color, additional decorations, and design features (Bravery et al. 2006). Some aspects of bower building go beyond mere skill development. Researchers found not only great individual differences and preferences in design but also individual insistence on maintaining their design. If some decoration pieces are removed, males compensate for such loss by increasing bower construction behavior and hastening bower painting. In other words, males are able to assess the quality of their own displays and make decisions about how to augment them. It also seems that females choose bowers not just for their decorations but also for the male’s display at the bower. It seems that the artistic forms of the construction inspire both male and female choice.

The display of the great bowerbird’s court (the areas in front and at the back of the bower) is particularly interesting because it is, in fact, purposely deceptive. Its building strategy is to create a visual illusion. The female is asked to judge the male’s achievement by the visual perspective of the court (Kelley and Endler 2012). The bird arranges the pebbles from large to small from inside to outside in a reverse way (smaller pebbles in front, large in the back) creating a visual illusion known as a forced perspective. The female viewing the male’s display over the court apparently judges the perspective and the quality of the illusion as the most important variable.

### **Use of Sticks and Implements Generally**

The distinction is usually made between proto-tool use and true tool use. Proto-tool use is not in itself a tool but indirectly an aid to achieve something else – for instance, wedging a nut between the fork of a tree steadies the nut and enables the bird to hammer away at the nut until it breaks. Proto-tool use is considered the cognitively simpler form of tool using but can be quite ingenious in helping an individual to obtain food from a source that may be enclosed by a hard shell or, if a caterpillar, has biting or toxic parts. Using an

appropriate substrate (or spear the prey on a thorn) can help to complete the task, remove the shell or the biting parts.

The list of passerines having perfected such techniques is quite long, and such behavior has been observed on every continent. Nearly all ravens and crows worldwide have been observed to use proto-tools and true tools. There is an interim group that has usually been fitted into proto-tool use, but it seems quite remarkable. Quite a number of birds have learned to use bread as a bait for fish. Since such species (observed in herons, Australian ravens, and many others) could readily consume the bread, the birds would have to inhibit their own appetite for the bread for something better (often called deferred gratification). That is, the bird has learned not just what is edible but that it can use the more inferior food if it is willing to risk the loss of this food morsel or something qualitatively better (as a fish) and possibly even larger than the food already in hand (Kaplan 2015). True tool use, by contrast, means that an implement has to be used in order to achieve an outcome that could not be done by the bird without such a tool.

As the tasks get more complicated, the number of passerine species engaging in true tool using behavior dwindles, although the number of ravens and crows (and of the entire widespread corvid family) tends to remain constant. Another, more ingenious way is to drop the prey item onto some substrate. For instance, an egg can be broken easily this way without falling apart, depending on the height chosen of course, enabling the thief (they have to steal it from a breeding species) to keep most or all of the contents inside the shell so that it can be accessed by the bird. Crows in Japan have learned to throw nuts on the road and let car tires crush the nuts for them.

Innovations or spontaneous choices in birds sometimes surprise because of their ingenuity. In England, the great spotted woodpecker (*Dendrocopos major*) has been observed in the wild to peck on a public-address system to amplify its sounds specifically in the direction of a conspecific. In the laboratory, great spotted

woodpeckers have been shown to be capable of cognitive tasks of a complexity matching that found in crows and parrots, so this specific behavior actually fits into a broader scale of cognitively more abstract behavior in this particular species. However, choosing a public-address system to enhance its own impact of an auditory message is a clever trick, but it is used by many animals. For instance, large Australian tree frog males preferentially choose to sit in downpipes of houses where their croaking is substantially amplified and helps to advertise their territoriality or impress a potential partner.

True tool use, for instance, may involve picking up sticks and holding it in the beak to probe for ants, just as do great apes. Birds may use empty shells to prise open a mussel (as white-winged choughs do, *Corcorax melanorhamphus*) or collect and carry sticks to another site as varied sittellas do (*Daphoenositta chrysoptera*) indicating that the bird had a specific goal and has taken the appropriate equipment to the “job site” where retrieval of a wood borer is expected to occur or hoped for. Blackbirds, *Turdus merula*, use tufts of twigs as a broom to remove loose snow cover when trying to find food. Regent bowerbirds are known to use wads of greenish leaves as “paint-brushes” to help change the coloration of the bower, representing a well-known example of tool using by birds. New Caledonian crows and woodpecker finches habitually use and manufacture tools in the wild. New Caledonian crows have also been shown to be capable of tool selection, and modification, and meta-tool use (i.e., using one tool to access another tool to access food).

In a recent set of experiments, the investigators compared two similar-sized (medium) and highly successful passerines in a range of foraging tasks, one an introduced Indian myna, *Acridotheres tristis*, belonging to the starling family, and the noisy miner, *Manorina melanocephala*, a honey-eater (Griffin and Diquelou 2015). They found that, in Australia, Indian mynas were significantly more neophobic than noisy miners, not surprisingly since there are various programs for their culling in place (they are an introduced species). However, in innovative foraging tasks, Indian

mynas consistently outperformed noisy miners. The ability to use the beak in a greater range of ways, and more flexibly, was highly repeatable in Indian mynas and underpinned their superior problem-solving performance. They also found significant differences in motor diversity and motor flexibility between the two species. Their findings raise an important point about the physical ability of a species and its relationship to cognition. Motor flexibility and even motor diversity proved to be factors that were significantly and negatively correlated with the speed of solving a task. It could be argued then that the differential results between noisy minors and Indian mynas may have nothing to do with more or less complex cognition but with the design and function of the bird's anatomical structure, here the beak (Griffin and Diquelou 2015).

Field observations of tool use in many passerines worldwide have raised the question as to whether passerines can take this tool using a step further by presenting them with a problem that can only be solved when they use reasoning. The most well-known and most frequently used laboratory tests are the tube tests, the means-ends test, and, more complicated, tests that replicate the Aesop's fable of raising the water level in a glass to obtain a floating food item. Equally well tested is tool adaptation or tool selection to obtain a food morsel (see Fig. 10).

### Laboratory Studies – Means-Ends Tests and Others

The means-end test has been used in a number of ways, but the basic principle is the same – a favorite food is affixed to the end of one string, and then another string that overlays it in an angle has a stone or some other inedible item of a similar size as the food morsel attached to it. The two strings are then crossed in such a way that the one end closer to the bird actually has a stone attached and, visually, the favorite food item is in line with the wrong string. If the bird follows just visual markers, it should spontaneously choose the wrong string, but if it had followed the line of the string from the favorite food item back to the end of the string that it can reach, it will choose the right one. Indeed, both seedeaters and insectivorous passerines can do this easily ranging from some of the smallest (zebra finches, sparrows) to the largest passerines (ravens). This test is also rather close to avian natural behavior and is possibly a circumstance seedeaters and even insectivorous birds may encounter periodically.

The tube test, used as another standard piece of testing equipment (Fig. 10), has a favorite food item placed in a transparent tube that is open at both ends. The bird has to use an implement and has to figure out from which end it needs to approach the task because one side will have a hole at the bottom and if the bird chooses this one,

**Passerine Cognition, Fig. 10 Solving problems of access to food. A** Means-ends test – zebra finch needs to pull string and chooses the correct one (a). **B** Tube test in

various configurations with implement; **C** rooks understand how to raise water level or adapt tool to retrieve food (part C adapted from Jelbert et al. PLOS one, 2014)

the food raked in (or pushed out from the other side) with an implement which will drop through the hole and make the food item irretrievably lost. The tests establish whether the subject of the test recognizes which tube is complete and will allow the individual to maneuver the food safely by choosing the right direction for extracting the food. This is a far more difficult test, and many birds fail, possibly for not being able to manipulate the relatively long implement all that well (again – the shape of the beak and its function may be an important factor) or because the hole in the bottom of the tube was not spotted or the consequences of the food falling into the hole were not fully understood.

Cognitively very demanding, and more than just a grade of difficulty harder, is the floating peanut test which presupposes an understanding that rocks can displace water and hence make the water level in the tube rise. A number of recent investigations using the floating peanut test were conducted with rooks and with New Caledonian crows (Fig. 10). The crows solved the physical problem and used the stones to raise the water level to a height where their beaks could reach and retrieve the floating nut. This water displacement principle is an important physics principle but rather beyond comprehension for human children under 6 years of age. It has puzzled researchers for some time why children even as old as 8 years, and with extra help given, have such difficulty in solving a problem at a time when they already use basic implements (Cutting et al. 2014).

Finally, another test involves adapting a tool to fit the purpose. A tube without water has a peanut placed at the bottom of it and several items are placed next to it. When the bird makes the right choice and bends the end of the wire, it can hook up the peanut and lift it out of the tube. Again, this is a task children of 8–9 years old may still find difficult to solve but not ravens. Of course, there is the less elegant but equally effective method that Australian magpies use when confronted with this problem – they simply upend the tube, and the peanut drops out!

There are many simple tests that can be conducted in a laboratory that may suggest how

well a bird has understood and used, or gone beyond, its basic “tool kit” of knowledge of geometry, mathematics, or physics and how well it can predict the outcome of its actions.

## **Behavioral Evidence of Concepts of Past, Present, and Future**

The idea of having a concept of time was thought to be uniquely human. It was believed, almost until the turn from the twentieth to twenty-first century, that the only existence animals knew was in the present. Disproving such a belief scientifically, however, is difficult because time is by its very nature fleeting and abstract. The research that commenced in the 1990s on memory of past events in passerines was ingenious, logical, and scientifically plausible. Researchers picked as their subject birds that were known to hoard food. There are different ways of hoarding food. One is to transport food items to a fixed larder. Hoarding a supply of food for winter months underground or depositing food in a hollow or making holes in the bark of a tree and inserting pine nuts, as woodpeckers do, is a rather widespread phenomenon. This behavior could be triggered simply by changes in temperature and may provide little if any hints as to whether the birds have understood that their present behavior is based on past experience, let alone whether there is any sense of future.

There is another type of food hoarding, however, called scatter-hoarding found in nutcrackers and several species of jays. In those cases, the individual birds take nuts in autumn and hide them in widely dispersed positions across the ground. Researchers rightly assumed that if any species could demonstrate that they have a concrete memory of specific past events, it had to be those species whose survival in the harsh winter months depended entirely on the recovery of food items they had hidden in autumn. Importantly, such hoarding behavior had to include a memory of past actions and events. This process could also be tested experimentally. It is called episodic memory, indicating that a bird may be able to record and remember specific events of the past

and act on that memory in the present. It was possible to measure what the Clark's nutcracker actually did. It was found that it can successfully retrieve as many as 30,000 pine nuts in a season and retrieve more than 90%, a truly remarkable feat. The birds do so by using cognitive spatial maps: that is, using geometry rather than simply remembering the details or landmarks. The latter would not help since snow cover dramatically alters landmark appearances.

Experiments using western scrub jays (*Aphelocoma coerulescens*), part of the larger corvid family, suggested even more strongly that there was more at work than merely memory of geometry. The birds regularly experience conspecific onlookers spying on their activities with the clear intent of stealing the cache. Hence, to hide food in the presence of others is risky and requires re-hiding when a potential competitor has witnessed the caching. Scrub jays, moreover, will cache both perishable and imperishable food, and they retrieve the perishable food first indicating that they remember what they have stored, where they stored it, and when they stored it (Clayton and Dickinson 1998) fulfilling the three important ingredients of episodic memory (what, where, when). The ability to remember the exact and general location of the hidden items for days has also been tested in pinyon jays (*Gymnorhinus cyanocephalus*). The birds watching someone hide a piece of food could remember the location of caches made by the observed bird even 2 days later and even 7 days later searched in the correct general locations. There is a further and specific dimension of time concerning the perishability of food itself.

Similar studies have been conducted with black-capped chickadees (*Parus atricapillus*) and most other tits in the family Paridae, as well as nuthatches (family Sittidae), and magpies, *Pica pica*. They too store food in cache sites scattered through their home range and may create several hundred such sites in a day. They never reuse the same cache site and retrieve their stored food after a few days by remembering the precise spatial locations of their caches. In all the cases recorded,

it was found that the birds used a cognitive spatial map.

One can also argue that by extending the ability to stash valuable resources for the future and not for current consumption, there is a clear extension of the time frame. Hence, episodic memory is associated with future planning which then raises the entire spectrum of time from the past to the future, a fact that finally answered the question whether passerines merely live in the present. They do not (Raby et al. 2007).

There are also passerine species, chiefly but not exclusively the honeyeaters, which do not cache their food but rather rely on a food source that has its own ebbs and flows of availability, and these are all the nectar-producing plants. When a supply has been depleted, it takes some time for the resource to replenish. Birds must remember what they found, where it happened, and even when they found it. They must also learn about the intervals at which this food source replenishes.

The now thoroughly disproved Bischof-Köhler hypothesis that only humans can dissociate themselves from their current context and take action for future needs sounds quite hollow in the twenty-first century because we know that passerines plan for the future in a variety of ways. There are ways of thinking about the future other than food and even in areas that are far more abstract: it has been shown that this is possible but depends on a social context, which will be raised in the next section.

## Social Brain and Memory

What is it about couples and specific groups that may enhance cognitive ability? Swallows and martins have communal activities including nest material collection and social flights in morning and evening, orioles sometimes bathe together, apostle birds and babblers do everything as a group, and finches and many other passerines may have large social gatherings. Superb blue wren males may form "clubs" to support

extramarital activities, and males may help raise offspring not their own, and many avian species engage in social drinking (Kaplan 2015). Yet some of these communal activities remain at the level of aggregation and may neither enhance communication nor social cohesion.

The question occupying researchers is whether activity-based social behavior has an impact on cognition. Indeed, a recent paper showed that, in woodpeckers (Picidae), living in stable social groups is associated with a *reduction* in brain size. The authors explain that multiple and reliable sets of eyes and minds reduce the need for extravagant brain power (Fedorova et al. 2017). Picidae (woodpeckers) are not passerines (two toes forward and two back), and they do not sing. Perhaps this suggests that it is important to consider brain differences and how they have arisen in different orders.

Most passerines live in some kind of social group. Indeed, one of the most remarkable aspects about bird life is that close to 90% of passerines (as against 5% of mammals) raise offspring together as a pair. A fraction of them has opted for a cooperative model, meaning that offspring of previous years provide additional help at feeding the new generations of nestlings. It depends what functions such a group may have and whether such groups can be called “social.” Sociality is an important topic in primatology, but it took some time for ornithology to establish the view that many birds are extremely social and that “social” meant a specialized form of communication that goes well beyond observed incidents of flocking and loose aggregations of nesting colonies.

Group living and cooperative passerine species, as well as similar social arrangements in primates, have given rise to the assumption that brain power and cognitive abilities increase with greater and more long-term partner cohesion than in loosely bonded groups or frequently changing partnerships. The social brain hypothesis arose out of these assumptions arguing that the major functional role of the vertebrate telencephalon is the regulation of social interaction.

This hypothesis raises an important question: What does a community of animals gain from being a community? The reasons for colonies of birds nesting together are well documented. There are safety in numbers and the likelihood that more offspring survive if thousands of them hatch at the same time. Equally, large numbers may act as a safeguard against predators generally. It is little more than that.

There are social behaviors that seem to go further and signify communication and information sharing that may benefit everyone in the group and lead to better survival rates and improvements in foraging and other areas. Information sharing can benefit generation after generation of bird groups. Active information sharing with conspecifics may be used to reduce exposure to risk. Sasaki and Biro (2016) investigated such stable communities describing the emergence of a cumulative culture from collective intelligence with the important rider that such group activity tends to increase efficiency over time but not necessarily complexity. Yet what the accumulation of knowledge achieves is that it exceeds the capacities of single individuals and that such a framework in turn may, at times, throw up exceptional innovations or individual innovators.

The social brain hypothesis has fitted well around ravens and crows because they fulfill all criteria – living in close-knit groups, having large brains, and, moreover, showing genuine, sometimes even altruistic ways of dealing with conspecifics, such as bartering, consoling a defeated mate, sharing, and even resorting to reciprocal altruism. If one looked for an example of the relationship between cognition and social life, it is amply and well demonstrated in corvids. Quite a number of birds apart from ravens and Australian magpies, even chicken not belonging to passerines, can distinguish individuals.

Common ravens and rooks have been shown to exchange coalitionary support among bonded friends, which may be expressed by approaching and grooming the other in order for the groomer to secure support later. Of course, such subtle social interactions presume that they know and

**Passerine Cognition, Fig. 11 Interactive postures in Australian magpie families.** This is just one interaction following unacceptable behavior by a juvenile, having snatched some food ahead of the adults. The above panel shows the first consequence: the adult male (the father) shows rising anger not just indicated by the erect body posture but by the feathers rising on his back. The offspring shows submissive behavior by curving its back downward and crouching (just as Charles Darwin had first illustrated in dogs), keeping the head down and tilted and thus putting himself straight into the line of fire by risking a peck, and by doing so, he may, in fact, not get physically punished.

The offspring plays a very different game with the adult females (including his mother). Females usually do not engage in physical punishment. The females, note the three females all face the offending youngster, are also erect in posture, and one even vocalizes in disapproval – the offspring adopts a posture as a nestling and the “cutest” it can possibly manage. In both cases, the strategy succeeded and the adults eventually left. However, a further transgression may, in fact, result in physical punishment. Usually, the juvenile has learned the lesson and won’t repeat the same transgression (but may well commit others)

recognize each other and treat each other not just as individuals but as “significant others,” and we know this because their vocal communication has been studied in detail (Kaplan 2014). Such studies revealed, in common ravens and in Australian magpies, that these vocalizations carry individual characteristics which are recognized by group members (Kaplan 2019). It has recently been discovered that ravens even remember the nature of a single reciprocal interaction sequence over 2 days and even after a month (Müller et al. 2017). In general folklore, one speaks of raven groups as a “parliament” of ravens as if to suggest that they were able to control impulses and make rational and informed decisions, i.e., approaching a quality that is thought to be unique to humans. Indeed, research into passerine cognition has given us an inkling that some passerines may indeed show behavior that approaches rationality.

Often not discussed are the nonvocal forms of communication. Charles Darwin (1904) was fully aware of the complex range of body postures and movements as expression of social dynamics, be this in the context of strict social hierarchies or, perhaps even more so, in rather egalitarian partnerships especially when monogamous or as life-long partnerships. Passerine species with long-term pair or group commitments have often developed a rich range of vocal and nonvocal signals that are clearly understood and can be regulatory or supportive (Fig. 11).

Intimate levels of complex interactions observed in the bird world may well rival those of subtle interactions in troops of chimpanzees, elephant families, wolf packs, and pods of cetaceans, and it suggests that avian cognition in general, and passerine cognition in particular, is an exciting field that has just begun to reveal some of the birds’ cognitive attributes.

The discovery of the broad range of cognitive behavior in passerines has been a beacon for reassessing how evolution works and how even birds, once thought simple mechanistic organisms driven only by instinct, might need a cognitive tool kit to survive. These “tool kits” have been extended into the complex social domain, into long-term memories and knowledge of past events and of a future dimension, and even into the realms of strong allegiances among families and engaging in behavior that suggests empathy and personal conflict resolutions. The results so far available about passerine cognition are very important because they have utterly challenged the idea that evolution has favored the primate line as the only carriers of “intelligence” in the broader sense (called the g factor loading of cognition). The robust findings have undermined the view of *scala naturae* when applied to cognition and finally utterly destroyed the Cartesian notion that animals cannot think, a claim that a philosopher, Rene Descartes, had so brazenly made some 400 years ago. The latter’s dictum which had colored our way of thinking about animals in general well into the twentieth century has been disproven.

## Passerine Life History

David V. Gesicki

Department of Biological Sciences, Bowling  
Green State University, Bowling Green,  
OH, USA

## Synonyms

Growth; Perching birds; Reproduction; Survival

## Definition

Passerine life history describes the reproduction, growth, and survival patterns of the avian order Passeriformes, which includes two principal suborders, Tyranni (suboscines) and Passeri (oscines or songbirds), in addition to the basal suborder Acanthisitti (New Zealand wrens).

## Introduction

Perching birds called passerines represent a diverse and species-rich order of mostly small land birds. Defining characteristics of passerines include unique oil glands, spermatozoa, forelimb and hindlimb musculature, and an enlarged flexible hind toe (hallux). Many passerines exhibit unique behaviors and physiologies and possess relatively large brains and superior learning capabilities particularly with respect to vocalization richness and song learning within the suborder Passeri. The behavioral plasticity and learning abilities of passerine birds very likely gave them an advantage over non-passerine competitors that explains their success being the most species-rich order of birds, constituting more than half of all species of birds worldwide. Passerines are generally short-lived and highly social often forming same or mixed-species flocks. Fundamental differences in the anatomy of the syrinx distinguish between suborders of passerines: the suboscines (Tyranni) and the oscines or songbirds (Passeri) (Raikow and Bledsoe 2000). However, recent studies have suggested that New Zealand wrens (family Acanthisittidae) form a third, more ancient, suborder, Acanthisitti, with no living close relatives (Ericson et al. 2002). New Zealand wrens are called “wrens” due to similarities in appearance and behavior to the true wrens (Troglodytidae) of the suborder Passeri but are not members of that family. This chapter addresses key life history traits for passerines, although at times closely related orders are mentioned, focusing primarily on reproduction, growth, and survival. A more thorough account of avian cognition is covered elsewhere within

this encyclopedia and therefore will not be addressed in any depth here.

However, a discussion on avian life history would be lacking without a brief mention of the remarkable intelligence of birds. Research over the past 50 years has shown that historical views on bird intelligence, emphasizing that avian behavior is stereotyped, are incorrect. Studies have demonstrated that birds possess considerable behavioral adaptability when foraging, communicating, selecting mates, interacting in social groups, and avoiding predation (see Krebs and Davies 1984). It is clear that using information about the environment to guide behavior can have large effects on biological success or fitness. But to acquire such knowledge, a bird needs to have had suitable experiences and possess the cognitive mechanisms necessary to transfer experiences into knowledge that can then be used in the future (Balda et al. 1996).

## Reproduction

### Mating

Many species of birds are sexually dimorphic in color or color patterns. Sexual dimorphism with respect to plumage color is considered to be a consequence of sexual selection (Hamilton and Zuk 1982). Variation in the extent of sexual dimorphism among passerine species is typically attributed to differences in mating systems. For example, sexual dimorphism in passerines can take on many different forms; male and female corn buntings (*Miliaria calandra*) have nearly identical plumage, but males are typically 40% heavier than females. Male and female American redstarts (*Setophaga ruticilla*) are similar sizes, but the dark black and orange plumage of the males is unlike the drab grey, greens, and yellows of the female (Fig. 1).

Researchers agree that passerines typically conform to social monogamy where individuals pair bond with a single member of the opposite sex. Approximately 92% of all bird species exhibit monogamy. Multiple mating systems have been observed in passerines though polygyny, in which males mate with several females

**Passerine Life History, Fig. 1** Photograph of male (a) and female (b) American redstart (*Setophaga ruticilla*; Photo by D.V. Gesicki)

(but each female mates with only one male), and polyandry, in which females associate with several males, have been observed in passerines. The dunnock (*Prunella modularis*) is unique among all birds because they possess variable mating systems. Female dunnocks are often polyandrous, breeding with two or more males at once. This mating behavior has led to the development of robust sperm competition among males. Males attempt to ensure their paternity by pecking at the cloaca of the female to stimulate ejection of rival male sperm (Davies 1983). Other mating systems also exist within dunnock populations and depend on the sex ratio of individuals in the population and territorial overlap. Based on knowledge of territory quality and sex ratio, dunnocks adjust their mating systems, adopting monogamy, polyandry, or polygyny when each system would seem advantageous (Davies and Houston 1986; Hatchwell and Davies 1992). Individual dunnocks seemingly adjust their social behavior depending on a cognitive assessment of several environmental and social parameters.

Promiscuity and extra-pair copulations have been reported in monogamous species, polygynous species, and polyandrous species. Extra-pair copulations are defined as copulations with an individual(s) other than a mate or social partner. The percent of extra-pair young in avian populations may range from 0% to more than

50%, but in many songbird populations, the percentage of extra-pair young is typically between 10% and 25% suggesting that at least some individuals in a population benefit from extra-pair copulations (Griffith et al. 2002). At one extreme, in the cooperatively breeding superb fairy-wren (*Malurus cyaneus*), it has been shown that other males may father 72% of offspring and that 95% of broods contained extra-pair young (Double et al. 1997; Double and Cockburn 2000). Domestic canaries (*Serinus canaria*), a species known for not having high social cognitive abilities, have been shown to subtly adapt their behavior to the current social environment. In one study, male canaries actively tried to conceal their extra-pair courtships in the presence of their mate and were observed to increase aggression toward other males when their mate was watching (Ung et al. 2011).

### Parental Care

The avian egg is a remarkable structure; it provides not only nourishment for the developing embryo but also proper ventilation, insulation, resistance to temperature fluctuations, and protection. After fertilization, the egg with its embryo pass through the oviduct, where albumen and a hard shell made of calcium carbonate are added to the developing egg, a process that takes from 1 to 7 days. Some birds have fixed clutch sizes; the

clutch size is the number of eggs a bird lays in one set. Variations in clutch size reflect genetic differences between individuals in addition to age, resource availability, geographic region, and season. For example, observed average clutch sizes across populations of passerines show a strong geographic gradient from an average of 4.5 eggs at the high northern latitudes to just over two eggs per brood in the tropics (Jetz et al. 2008). Incubation is the process by which the temperature of eggs is maintained via heat exchange from the brood patch suitable for embryonic development; most birds exhibit biparental care. Nest attentiveness or the percentage of time spent on the nest during incubation is an example of parent-offspring conflict. Incubating birds must balance a trade-off between caring for eggs by staying on the nest versus caring for themselves by getting off the nest to forage. After hatching, parental care involves brooding and feeding nestlings as well as protecting young from predators. All passerines give birth to altricial young. Altricial young are naked, blind, and virtually immobile when they hatch and thus are completely dependent on their parents. Interestingly, it has been suggested that altricial development is only possible because passerines have evolved the ability to construct a nest, which protects chicks from predators and from poor weather. Only a few species, for example, brood parasites, exhibit no post-hatching parental care.

### Brood Parasitism

Avian brood parasitism, or the laying of one's eggs in the nest of another individual, is a reproductive strategy in which one imposes the costs of incubation and rearing of young onto another individual, the host (Davies 2000). Brood parasitism may be either obligate when all the eggs are laid in the nests of other individuals or facultative when some eggs are incubated by the parents and other eggs laid in the nests of other individuals. Facultative brood parasitism is uncommon in altricial birds but is widespread in precocial waterfowl. Brood parasitism may also be intra-specific, with eggs laid in the nests of a parasite's own species, or interspecific, with eggs laid in the

nests of other species. Obligate interspecific brood parasitism has evolved at least seven separate times among various avian clades, including twice within the order Passeriformes (cowbirds (Icteridae) and indigobirds and whydahs (Viduidae)). The benefits for the parasite include increased fecundity as more effort can be directed toward mating and producing eggs rather than building and defending nests, incubating eggs, and feeding young. For hosts the costs include diminished nestling growth rates due to nestling competition with the often-larger parasitic offspring, total abandonment of parasitized broods, eviction of all host eggs by the earlier hatching parasites, or the killing of host hatchlings by parasitic hatchlings (Kilner 2005; Servedio and Hauber 2006). These costs exert selective pressure on hosts to evolve defenses to discriminate against parasitic eggs or hatchlings based on visual and acoustic cues (Cassey et al. 2008).

## Growth

### Hatching and Neonate Size

Hatching, the breaking of the eggshell and emerging from it, is a physical challenge. Postembryonic development before hatching is when the basic systems of life are established, including a skeleton made first of cartilage and then calcified, a digestive system that sets limits on energy intake, a brain that will continue to grow, and a feathered integument. At the time of hatching, the chick barely seems to fit inside the tight confines of the eggshell. To break out of the egg the chick shifts its position within the inner membrane of the egg and begins pipping or pecking regularly at the shell. After 1–2 days, the chick breaks through the eggshell emerging to the outside world. Eggs in a clutch may hatch synchronously or asynchronously at intervals that may range from a few hours to more than a week (Clark and Wilson 1981).

### Patterns of Growth

A typical passerine hatchling's growth of body mass during development follows an S-shaped

logistic curve. At first the young bird grows slowly, then the growth rate accelerates and mass increases rapidly, and, finally, growth decelerates as the bird's weight reaches that of the adult. There are two distinct exceptions to the typical shape of the growth curve. The mass of highly aerial species, such as the American cliff swallow (*Petrochelidon pyrrhonota*), overshoots the adult mass during the final stages of development before juveniles have learned foraging techniques. Body mass then declines as a result of changes in metabolism and water loss as the result of tissue maturation in the skin. The second exception is in ground-feeding birds such as the curve-billed thrasher (*Toxostoma curvirostre*) where chick mass stabilizes below adult mass (Ricklefs 1965). Ground feeding chicks achieve full size after fledging when their plumage and muscle development catch up with their skeletal development. Altricial species, in comparison to semiprecocial or precocial species, generally exhibit faster development and tissue maturation. Individuals of a species can show markedly different growth rates and generally nestling growth rates often decline as brood size increases (Klomp 1970). Perhaps best known in swifts and martins, maturation rate varies with the quality and quantity of food, temporal patterns of feeding, and temperature. For example, maturation of common swifts (order Apodiformes *Apus Apus*) varies from 37 to 56 days, depending on food availability (Koskimies 1948).

### Maximum Size

The maximum size of passerines relates to the costs of flight, which is influenced by the relationship between total wing area and body mass. The relationship between wing area and body mass, called wing loading, is given in grams per square centimeter of wing surface area. Considerable data on the subject of wing loading has been collected from European and North American species. Small passerines have rather large wings and, consequently, low wing loadings. For example, the ruby-crowned kinglet (*Regulus calendula*) has a wing loading of, on average, 0.11 grams per square centimeter. Among North American passerines, the American

crow (*Corvus brachyrhynchos*) has one of the highest wing loading of about 0.41 grams per square centimeter (Poole 1938). Although wing lengths and surface areas increase typically with mass among birds, the increase is less than expected to maintain a constant wing loading. The wing area increases as the product of the length and width of the wing's surface, whereas body mass increases with volume. Therefore, wing area must increase at a rate of 1.5 times for each single unit of increase in mass. The theoretical upper limit therefore for birds is around 2.5 grams per square centimeter. At this point most birds cannot generate sufficient lift with their wings to overcome drag and gravity. Worldwide, the thick-billed raven (*Corvus crassirostris*) has the distinction of being the heaviest passerine weighing approximately 1.15 kg in females and 1.5 kg in males and the smallest being the short-tailed pygmy-tyrant (*Myiornis ecaudatus*) with an average weight of 4.2 grams (g).

### Feathers and Molt

Among passerines, feathers are essential for flight in addition to providing thermal insulation and waterproofing. Feathers play further roles in communication, courtship, and competition for mates and in predator avoidance through camouflage. Although growing feathers are vascularized, mature feathers are dead structures and cannot be repaired. Feathers may become damaged during encounters with rivals, predators or prey, or through normal wear and tear and must be replaced. Molt, the systematic replacement of worn and damaged feathers, is essential to birds. In some species, however, molt serves an additional purpose as it allows birds to change their appearance to suit their needs at a given stage of their life cycle. For example, males of many passerine species annually molt all or some of their feather to shift from a non-breeding plumage to a breeding plumage. Molt strategies are often related to migratory behavior. Among old world warblers (*Sylvia*), species or populations that are relatively sedentary tend to spend a longer time on their molts than species or populations which migrate (Ginn and Melville 1983; Holmgren and Hedenström 1995).

## Survival

### Longevity

Determining aspects of passerine survival can be a challenge given the difficulty in following birds, particularly migratory species, over extended periods of time and considerably large distances. Rates of annual survival change dramatically with age across the first years of life. A young bird's chance of survival to a breeding age is typically about half the rate of adult annual mortality. Once juveniles reach adulthood, their chances of survival increase and stay relatively constant. Annual survival rates of small land birds vary from 30% to 65% per year (Ricklefs 1973). However, survival rates of adults do not remain constant. Carefully controlled studies of mortality among Florida scrub jays (*Aphelocoma coerulescens*) revealed increases in mortality at an average rate of 2% per year because of the degenerative effects of aging (Holmes and Austad 1995). The maximum lifespan of passerine birds can vary significantly. For example, the European goldcrest (*Regulus regulus*), a small member of the kinglet family, has an average lifespan of 3 years while the song thrush (*Turdus philomelos*) has an average lifespan of 13 years in the wild (Payevsky and Shapoval 2000).

### Predation

Predation is often hypothesized to be an important factor shaping the evolution of clutch sizes in birds (Perrins 1977) and is often thought to favor smaller clutch sizes. For example, it takes longer to lay a large clutch than a smaller one, which means that the parent and eggs of larger clutches are at risk for a longer period of time than those of smaller clutches. In the tropics, where most nests are lost to predators, smaller clutches may be advantageous as a mating pair of birds has the opportunity to re-establish nests several times throughout the year. The number of fledged young a parent can attend to or guard against predators may also limit clutch size in some birds (Yom-Tov 1974; Safriel 1975).

Adult birds often form flocks, a behavior that reduces the risk of predation and enables cooperative foraging. Stable food resources and

defensible spaces promote territoriality in birds, but unstable food resources and indefensible spaces will promote flocking behavior. Flocks can range in composition from loose temporary groups of a single species to highly organized foraging groups composed of multiple species. Multi-species flocks of tropical songbirds, which feed together throughout the year, are an example of a closed social system that actively exclude new members. A stable flock membership facilitates individual recognition and the development of dominance hierarchies (Hartzler 1970; Nilsson and Smith 1988). The safety of a large group enables individuals to relax their personal watch for predators, thus enabling them to feed more intensively.

### Movement Patterns

Migration allows for year-round activity. The advantage of migration is that birds can exploit seasonal feeding opportunities while living in favorable habitats and climates throughout the year. Migration clearly involves movement, but not all bird movements can be called migration. Migration is the regular, endogenously controlled, seasonal movement of birds between breeding and non-breeding areas (Salewski and Bruderer 2007). Some birds make less predictable, non-migratory movements in response to proximate environmental factors. Such movements are often referred to as irruptions or nomadic movements rather than migration. For example, whenever spruce seeds are scarce or absent entirely over much of their breeding range in the boreal forests of northern Europe, large numbers of common crossbills (*Loxia curvirostra*) move long distances, often 1000 kms or more, toward southern and western Europe (Newton 1970). Irruptions are irregular, but not infrequent; at least 40 irruptions of common crossbills are known to have occurred between 1881 and 2000 (Newton 2006).

Migratory birds exhibit variation in the distance of their migratory journeys, with some short-distance migrants moving just a few hundred kilometers and some long-distance migrants traveling several thousand kilometers. Many factors can contribute to this variation in migration distance among different populations

and species. For example, among suboscines (Tyranni), migration distance is influenced by feeding behavior, with insectivorous species tending to migrate longer distances than frugivorous or granivorous (seed-eating) species (Boyle and Conway 2007). Because of the differences in the availability of prey, many insectivorous species breed at higher latitudes and migrate relatively long distances to winter at low latitudes.

### Feeding Ecology

Closely linked to migratory movement in many passerines is the location of food resources. Birds expend energy at a high rate and must feed frequently to refuel themselves. Adaptations for feeding are a conspicuous feature of avian evolution. Adaptations not only include those for flight but also anatomical specializations of the bill and tongue, legs and feet, crop, and stomach and intestines. Considerable research interest has been placed on the balance between feeding effort and energy requirements, and the role that learning plays in increasing foraging efficiency. Some bird species are also well known to store food reserves for later use, a behavior known as caching, and the sometimes-spectacular recovery of cached seeds highlights the extraordinary spatial memory ability of some granivorous species (Källander and Smith 1990).

A bird's bill or beak is its key adaptation for feeding. The size, shape, and strength of the bill dictate potential diets. True shrikes (*Laniidae*) are unique among passerines for being carnivorous and having strong, hooked beaks, which tear flesh and sinew. Crossbills (*Loxia*) are specialist feeders on conifer cones, and the unusual crossed-bill shape of their bills is an adaptation that enables them to extract seeds from cones. Seeds sustain a large variety of passerines and most passerines that specialize in seed-eating crack and shuck the seeds with powerful bills. However, birds lack teeth used to chew food before swallowing; therefore, the avian digestive system is specialized to process foods whole. The major parts of the digestive system, the oral cavity, esophagus, crop, stomach (including gizzard), liver, pancreas, intestines, and cloaca are further

specialized to accommodate particular diets and feeding behaviors. Linked with the evolution of flight and high metabolic rate, the digestive system of birds extracts nutrients and energy quickly and with high efficiency from small and quickly handled food (Castro et al. 1989; Afik and Karasov 1995). The avian gizzard is a large, strong, muscular structure primarily used for grinding and digesting tough food. Functionally equivalent to molar teeth in mammals, the gizzards of grain and seed-eating birds are especially large and have powerful muscles.

Unlike the study of the functional feeding anatomy of birds, the study of foraging behavior is more relatively more recent. Hoarding and hiding food for future use is one-way passerines prepare for food shortages (Vander Wall 1990; Källander and Smith 1990). Shrikes are notorious for impaling their prey on thorns for later consumption. Tits, chickadees, and titmice (*Paridae*) depend on autumn caches of seeds for winter feeding. Seed caches are more difficult to relocate than, for example, the impaled prey of shrikes, and the recovery of widely dispersed and concealed seed caches requires a robust spatial memory, which is processed in part by the hippocampus of the avian forebrain. Birds bias their foraging effort to sites where the most profitable feeding may occur, select prey of the size that enhances their energetic profit, and innovate unusual foraging techniques including, in a few species using tools (Hunt 1996; Emery and Clayton 2009).

### Conclusion

Order Passeriformes includes suboscines, oscines also commonly known as songbirds, and New Zealand wrens and represents more than half of all bird species worldwide with representatives on all continents except Antarctica. While all passerines are generally short-lived and highly social, the diversity of species within this order makes it difficult to make generalizations about their life history traits or behavior. However, because of their charismatic nature, high diversity, generally small size, and relative ease of

observation, collection and field study of passerines have historically attracted the attention of a wide range of biologists, including systematists, behavioral ecologists, and evolutionary biologists. Variability in ecological and social conditions contributes greatly to the diversity of passerine species. The diversity of life history traits helps to understand the main selection pressures that passerines are facing in addition to why and how they have become adapted to their environment. The above sections are a board overview of aspects of passerine life history, which conveys the rich species diversity of this avian order.

## Definition

Movement used by the order Passeriformes (e.g., crows, finches, songbirds, swallow, wren, and bluebirds) to travel throughout their environment.

Passerines make up 60% of all bird species (Barker 2014; Raikow 1982). Passerines can be found on every continent except Antarctica, but are most commonly observed in tropical regions. These birds take a liking to areas filled with trees, as most are arboreal (Raikow 1982). Within the Passeriformes, there are two suborders that further divide these birds by the structure of the vocal apparatus: Oscines and Suboscines. The suboscines are much more limited in species (i.e., flycatchers and the kingbirds) (Ohlson et al. 2013) compared to the much more specious oscines (i.e., “songbirds”) that are divided into 70 families (Barker 2014; Raikow 1982).

There are several characteristics that all passerines share despite the diversity within the order. Passerines are generally small in size, with the exception of the corvids and the lyrebirds, and most have large wings relative to their total body

mass (Polo and Carrascal 1999; Raikow 1982). Additionally, Passeriformes are characterized by having four toes where three are directed forward and one is directed backwards. The hind toe, called the hallux, is continuously pointed backwards and is incumbent, or non-elevated. This arrangement allows them to perch on different slender structures with ease. The anisodactyl foot evolved in arboreal species for the purpose of gripping branches, but passerines have evolved to use them to perch on many different structures. These birds can be observed traversing tree branches, telephone lines, fences and other structures that have narrow places to perch (Botelho et al. 2014; Feduccia 1967).

## Flight Biomechanics

Flight is the most common form of locomotion in the songbirds. All flight begins with the takeoff phase. This is reliant on both wing and leg kinematics. Many species rely on flapping their wings and running simultaneously to begin take off (Dial 2003; Parslew et al. 2018). Most of the velocity that is required for takeoff is provided by the legs. After takeoff is the flight phase. Flight is powered mainly by two proximal wing muscles: *m. pectoralis* and *m. supracoracoideus*. The pectoral muscles functions in depression and pronation of the wing while the *m. supracoracoideus* functions in elevation and supination of the wing. Most wing muscles are proximal within the forelimb to allow for a lighter wing that results in less fatigue when flapping. Distal wing muscles provide more of a functional role in fine tuning of movement rather production of force (Dial 2003).

The flight stroke consists of two main phases: the downstroke and the upstroke. The downstroke is when the wing is pulled downward producing lift. The subsequent upstroke, also known as recovery phase, is when the wing is pulled back up. This resets the position of the wing so that another downstroke can be performed. Downstroke is well conserved among many species. The great variation that occurs during the upstroke provides the basis of gait classification in flight (Tobalske, 2007). There are two main types of flying gait: vortex-ring gait and continuous-vortex

gait. In vortex-ring gait, the lift is provided mainly by the downstroke. During upstroke, the bird tucks back its wings to create less drag which renders the upstroke incapable of producing lift. In continuous-vortex gait there is lift produced in both downstroke and upstroke. Lift is produced in upstroke through the partial extension of the wings (Dial 2003; Tobalske 2007).

Most bird species do not flap continuously; they go through periods of flapping and non-flapping. This alternating pattern of flight is known as intermittent flight. This is effective at conserving energy and allowing the passerine's muscles to relax during a long flight. The non-flapping period of intermittent flight consists of gliding or bounding. Gliding is when the wings are held in the extended position. Bounding is when the wings are tucked against the body. This creates two different types of intermittent flight patterns: flap-bounding and flap-gliding. Flap-bounding is the most common type of intermittent flight that passerines exhibit. Passerines also have the ability to soar. This is a type of gliding that utilizes environmental conditions (e.g., wind currents) to power flight (Dial 2003; Tobalske 2007).

Wing kinematics differ depending on a bird's wing design and flight speed. The orientation of wing forces in birds is facilitated by joints that allow freedom of wing motion around the shoulder as well as wing flexion and extension. The freedom of motion around the shoulder occurs because of the hemi-sellar (or half-saddle) shoulder joint present in most modern birds, which can be modeled as a ball-and-socket joint (Parslew and Crowther 2010). The degrees of freedom are represented as three shoulder rotation angles which are: a stroke-plane angle, wing elevation-depression, and wing pronation-supination (Parslew and Crowther 2010).

Additionally, birds' wings consist of multiple skeletal segments that can be rotated around the respective joints to induce an active shape change, allowing for the flexion and extension of wings, towards and away from the body respectively (Parslew and Crowther 2010). This active shape change, also referred to as active morphing, is one mechanism by which the diversity of bird wings is increased. Changes in the dynamic wing shape

(i.e., wing morphing) can be both passive and active. Passive wing morphing involves transient shape changes during flight that are not a result of muscle activity, rather, they are influenced by the structural properties of the wing's anatomy and feathers (Altshuler et al. 2015). In contrast, active wing morphing occurs within wingbeats as a result of spreadable feathers, intrinsic wing joints, and intrinsic muscles (Altshuler et al. 2015). The spreading and folding of feathers in active morphing generates force, while their structural properties in passive morphing balances aerodynamic and behavioral demands.

In terms of intrinsic wing joints, motion can occur passively through inertial forces during flapping and actively through muscles. Most of the shape variation in wings can be described using three kinematic variables which are: wing folding/expanding, wing twisting, and wrist flexion or extension (Altshuler et al. 2015). In flapping flight, most birds fold the wing during the upstroke by flexing the elbow and adducting the wrist. This shortens the wing-span, lowering the inertial cost of moving the wing, and increases wing safety margins at high speeds or turbulence (Altshuler et al. 2015). Wing twisting is defined as a change in the angle of incidence along the length of the wing, which can occur either passively or actively. Passive twisting involves mechanical forces caused by the structural properties of the wings, while active wing twisting is achieved through pronation and supination of the wrist (Altshuler et al. 2015). Wrist flexion and extension occurs perpendicularly to the plane of the wing, allowing birds to bend their wings. Wing folding and wrist flexion often occur simultaneously and are referred to as wing flexion (Altshuler et al. 2015). Overall, wing flexion reduces exposed wing surface area and wing length decreasing drag and wing-tip velocity, which is useful during upstroke for weight support and propulsion (Parslew and Crowther 2010).

## Migratory Patterns

From a zoogeographical viewpoint, bird migration generally is composed of three elements: the

breeding range of the species, its passage routes, and its winter range (Busse 2001, 2019). For most birds, including many of the order Passeriformes, migration occurs in a seasonal latitudinal movement from north to south and vice versa. In some cases, summer and winter ranges can be separated by thousands of kilometers (Alerstam 1991; Alerstam et al. 2011). However, many bird species have been observed to also migrate relatively locally in an upslope or downslope movement referred to as altitudinal migration. Altitudinal migration is the seasonal movement whereby during the breeding season, there is an upslope movement from lower to higher elevations, and during the non-breeding season, a downslope movement from higher to lower elevations (Pageau et al. 2020). The associated advantages include a decreased risk of predation, avoidance of harsh conditions and tracking of food resources. Within the Passeriformes, 13% are described as altitudinal migrants. However, their migration process is difficult to study due to the variability involved. For example, even within the same species, there is a variation between those that are altitudinal migrants and those that are stationary. Additionally, altitudinal migration may not only occur as a mechanism for birds to reach breeding grounds; birds can also move up or downslope to reach molting grounds (Busse 2001; Pageau et al. 2020).

Pageau et al. (2020) explored the link between passerine migration and diet and observed that foraging guild is evolutionarily associated with altitudinal migration, but this relationship varies across zoogeographical regions. Pageau et al. (2020) demonstrated that passerines in the Nearctic region that were herbivores and omnivores were associated with altitudinal migration. In contrast, only omnivorous species were linked to altitudinal migration the Palearctic region.

## Bio-Inspiration

Avian flight has inspired flying robots used in reconnaissance missions that utilize a perch-and-stare mechanism. Inspired by the

adaptability of songbirds, the design is based on a landing mechanism capable of perching on curved surfaces. This allows the robot (equipped with cameras and other sensors) to land on inconspicuous surfaces involving horizontal or vertical planes. For songbirds, the anatomy of the foot and leg are particularly important in terms of perching. Bird feet are underactuated, allowing them to passively conform to the structure they are attempting to perch on, which also allows them to sleep while perching (Daler et al. 2013; Doyle et al. 2011; Estrada et al. 2014; Pope et al. 2016).

Songbirds also have an unusual locking mechanism whereby the tendon on the rear side of the ankle can automatically cause the toes to grip around a branch when the leg bends, thus allowing the sleeping bird to grip the perch without using any voluntary muscle effort. The more relaxed the bird, the more the leg bends and the tighter the grip. To let go of the perch and take off, the bird must actively straighten up (Parslew et al. 2018). This mechanism and associated anatomy would be key in the development of the flying robots. The design of the gripper is based on the anisodactyl toe arrangement that most songbirds have with three toes facing forward and one backward, and the weight of the rotorcraft is used to enable the grip mechanism. The goal of this avian-inspired approach would be to achieve the passive perching mechanism on drones that can land and remain “perched” on a variety of curved substrates (Daler et al. 2013; Doyle et al. 2011; Estrada et al. 2014; Pope et al. 2016).

## Conclusion

The passerines are a dynamic order of birds that have several different locomotor modes. These birds are known to be able to traverse narrow fences, branches, and phone wires with ease due to their foot structure. They are also able to fly and have distinct take off and flying phases. Further study of passerine locomotion and bird flight can improve the technology of flying robots.

## Passerines Share Many Traits with Other Types of Birds

In seeking to understand the traits that distinguish passerines from other types of birds, it is useful to consider them in light of the traits that distinguish birds from other groups of animals. Birds are warm-blooded (endothermic) vertebrates, meaning that they generate their own body heat rather than relying on the environment to maintain their body temperature, and their body structure includes a backbone. When we think of birds, features such as wings and eggs may leap to mind, but neither of those features is unique to birds. For example, bats and insects have wings, and egg laying is common across a wide range of animals such as fish and reptiles. When we

consider the adaptations that define birds, many are associated with the demands of flight, such as reduced weight and efficient power. Feathers, pneumatic bones (such as those found in the wing), and a highly efficient respiratory system are all adaptations that facilitate birds' ability to fly (reviewed in Rodewald et al. 2018).

Highly adapted avian structures afford many useful advantages. For example, large flight feathers, such as the primary feathers on the wing, enable birds to generate lift and thrust while also controlling their direction in the air. Other types of feathers are collectively called "plumage" and are a form of ornamentation that plays an important role in courtship and mate choice for many species. Much smaller feathers are collectively called "down" and line the body to provide very efficient insulation to prevent heat loss. Despite their differences in size and appearance, each of these types of feathers is made primarily of a protein called keratin and consists of a hollow shaft with small barbs branching off on either side of that central structure (reviewed in Butler and Rohwer 2018). These highly adapted structures were once thought to be homologous to reptilian scales based on similar composition and development. However, more recent research suggests that feathers evolved through a series of changes in the follicle from which feathers grow (Prum and Brush 2002). The origin of feathers remains a topic of ongoing research, but it is clear that they provide important advantages in terms of flight, ornamentation, and insulation (reviewed in Butler and Rohwer 2018).

Forelimbs are also highly adapted in birds, so much so that they have received the specialized name "wings." At first glance, a bird's wing and a human arm might not appear very similar; however, the skeletal structure is very similar in wings, arms, and forelimbs observed across different species of vertebrates (reviewed in Shubin 2009). The most proximal portion of the wing consists of the humerus (from the Latin for "shoulder"), and the more distal portion is formed by the ulna (from the Latin for "elbow") and radius bones. Proceeding distally from those bones, they are connected to carpal (from the Latin for "wrist") bones that are in turn connected to the bones that compose the

digits (from the Latin for "finger" or "toe"). The names given to these bones by anatomists make clear the parallels between the bones in an avian wing and those in your own arm.

In many species of birds, bones contain hollow spaces that are strengthened by networks of bony filaments called trabeculae (from the Latin for "beam") (reviewed in Voss and Pavia 2018). The hollow structure of these bones not only makes them lighter, it also makes them very resistant to bending and other forces that occur during the downstroke of the wing. This is important, as birds produce forces in excess of their body weight when they fly, and those forces are exerted by large muscles that attach to the bones of the wing. For example, contraction of the pectoralis muscle pulls on the humerus bone and causes the wing to be pulled down in the power stroke of flight. The joints that connect the bones of the wing also permit a wide range of movement, facilitating the power stroke, pulling the wing back up, and folding the wing to rest neatly against the body when the bird is not in flight (reviewed in Voss and Pavia 2018). These structural features of birds' wings – hollow, lightweight, agile, and strong – are ideal specializations for the challenges of flight in which weight is an obstacle and strength is essential.

The avian respiratory system is also highly specialized and adapted to meet the metabolic demands of flight. This system enables the movement of oxygen from air into the blood, and it performs this task very efficiently to enable the vigorous actions of flight. In humans, our lungs operate in a tidal system of air entering and leaving the lungs through inhaling and exhaling. The structure of avian lungs is very different, and air flows in a single direction across the surfaces that permit the exchange of gases (reviewed in Martinez Del Rio et al. 2018). Structures called air sacs and the muscles that control the movement of the rib cage act like bellows to move air through the avian lung, and the unidirectional movement of air across surfaces in the lungs enables birds to exchange nearly all the volume of their lungs in each breath. In contrast, humans and other mammals do not exhale all the volume of our lungs

each time, leading to residual “stale” oxygen-depleted air that then mixes with fresh air in the next inhalation. Complete turnover of air in each breath means that birds have a greater content of oxygen-rich air available to them. The movements of flight further enhance the movements that drive respiration, pumping air through the respiratory system even more forcefully than when the bird is at rest (Jenkins Jr. et al. 1988). This is especially beneficial, as it provides even greater exchange of gases at the time when the metabolic demand for oxygen is greatest.

Together with additional specializations that are not described here (reviewed in Rodewald et al. 2018), the features described above are conserved across nearly all species of birds. These traits distinguish birds from other types of animals, and that is recognized by the taxonomic description of birds as belonging to Class Aves. However, there can be huge differences between different types of birds. For example, ostriches and hummingbirds are both birds, but there are vast differences in their size, shape, ecology, and metabolism. When we parse birds into more finely divided groups, the next level of taxonomic rank beyond Class is Order, and the largest group of birds is the Order Passeriformes. These birds are more commonly called passerines or “perching birds,” and the properties that distinguish passerines from other birds are the focus of the next section.

### Passerine Birds (Order Passeriformes)

The group of birds called passerines includes approximately 140 families of taxonomic division and 6000 species, comprising approximately half of all species of birds that are alive today (Olalla-Tárraga et al. 2019; Raikow and Bledsoe 2000; Ricklefs 2012). These birds may be very familiar, as they are commonly active during the day and they include songbirds that are commonly seen in the wild, such as sparrows, finches, jays, chickadees, and wrens. Passerines take their name from the Latin name for sparrows and small birds like them (*passer*). They are a very successful group of organisms, flourishing in a very wide range of

habitats and occupying remarkably diverse ecological niches (Olalla-Tárraga et al. 2019; Raikow and Bledsoe 2000). They are typically smaller than members of other orders of birds, with the largest passerines being lyrebirds and ravens (typically around 1.5 kg and 70 cm in height) and the smallest being pygmy tyrants (typically around 4 g and 6 cm in height) (Unwin 2011). Most passerines are small- to medium-sized land-dwelling birds that feed primarily on insects, fruit, seeds, or nectar, and their morphology is generally well suited to a variety of foraging techniques and prey items (Ricklefs 2012).

### Unique Features of Passerine Morphology

Passerines are more commonly known as perching birds because the arrangement of their toes and hindlimb muscles facilitates them perching on twigs and branches. Across all groups of birds, the arrangement of toes on each foot is remarkably diverse (reviewed in Voss and Pavia 2018). Different groups can have not only different numbers of toes on each foot but also different arrangements of those toes. The arrangement in passerine birds includes three toes that point forward on the foot, one toe that points backward, and no webbing between any of the toes (Fig. 1). This arrangement is called *anisodactyl* (literally meaning “unequal digits”), and it facilitates birds grasping either horizontal or more upright perches such as branches and tree trunks.

Passerines are *digitigrade*, meaning that they walk on their toes rather than on the entire foot, so the point of contact with perching surfaces includes only the toes and not the rest of the foot (Fig. 1). The bones in the toes of passerine birds are attached to muscles that work together with the *anisodactyl* arrangement to facilitate the perching reflex. Those muscles include the *flexor digitorum longus*, which flexes the three forward-facing toes, and the *flexor hallucis longus*, which flexes the backward-facing toe (Fig. 1; as detailed in Raikow 1982). The flexor tendons run along the backward-facing (posterior) side of the main bone of the foot (*tibiotarsus*) and insert on the bottom

(plantar) portion of the digits. The tendon from the flexor digitorum longus attaches to each of the three forward-facing toes, and the tendon from the flexor hallucis attaches to the single backward-facing toe (some birds have interconnections between these tendons; detailed in Raikow 1982 and Raikow and Bledsoe 2000). Because of this arrangement, the forward- and backward-facing toes can be controlled separately, but coordinated contraction of the two flexor muscles causes each of the four toes to flex (extension of the toes is controlled by other mechanisms). This is the same sort of action as what occurs when you close your hand around an object in your grasp.

The arrangement of passerine toes and the associated muscles has implications for the way that those birds can use their hindlimbs. Because the toes can be contracted in a grasping motion, passerines can use their feet to hold items such as food or nest-building materials. The wide range of motion in the movements of each toe enables the bird to adapt its grasp to accommodate a wide range of sizes and shapes of different perching sites. Passerines also commonly use their feet and toes in other ways such as aggressive encounters or the precisely controlled movements that occur in preening. Some passerines, such as the Family Corvidae within the Order Passeriformes, are especially adept at these sorts of movements. These birds have been shown to have impressive intellectual abilities, as they are able to solve challenges that require them to employ concepts such as analogy and problem-solving (Smirnova et al. 2015). Corvids have also demonstrated the ability to use the agility afforded by the arrangement of their feet and toes to create rudimentary tools such as hooklike structures to retrieve food from a location that would otherwise be inaccessible to them (Hunt 1996).

The arrangement of the muscles and toes also plays a key role in how the toes function even when the associated muscles are not being actively contracted. When a passerine bird assumes the posture that we refer to as perching, it results in the ankle being bent and the bird's body weight resting on that bent joint (Fig. 1). When the bird bends its ankle (the tibiotarsal

joint), the tendons are pulled along the bottom portion of the foot. This is the same movement of the tendon that occurs when the muscles are contracted, but in this case the tendon moves because of a change in posture rather than an active contraction of the muscle. In either case, movement of the tendon causes the toes to flex. Therefore, when the bird is perched, it can relax its flexor muscles and yet still have the force of its body weight acting to bend the ankle and flex the toes. In that way, the bird is effectively gripping its perch even when it is not actively contracting its muscles. This anatomical arrangement gives rise to a very convenient advantage in that passerines can grip their perch, and this remain safely secured on their branch or other site, even when they are asleep.

## Variability of Passerine Morphology

Just as there is great diversity across all birds (Class Aves), there is also diversity among passerines (Order Passeriformes). That diversity is commonly characterized by comparing specific measurements from each type of bird. For example, these measurements can include beak size and shape, properties of the pectoralis muscle, measurements of the bones in the hindlimb, features of wing shape, and the size of feathers at specific locations on the body. In addition to this anatomical diversity, there are also differences in the behavior and ecology of different kinds of passerines. Those differences are commonly characterized by features of a bird's diet, foraging strategy, and habitat (Kennedy et al. 2020). The following sections describe aspects of the diversity that is found among passerine species and how those differences are thought to have enabled these birds to thrive in a wide range of ecological environments.

## Variability in Beak Morphology

The size and shape of beaks varies widely across passerine species. These differences are correlated with differences in diet and foraging modes, and

they are thought to have played key roles in diversification of species (Mallarino et al. 2012). Differences in beak morphology, such as length or depth of the beak, can enable birds to adapt to diverse and changing ecological niches by enabling them to exploit different sources of a similar type of food. For example, seeds are important food sources for many passerine species, and beaks of different shapes and sizes may provide birds with varying degrees of success in accessing seeds such as those that are large and tough (for which a short and large beak may facilitate cracking those seeds) or that are hidden within the recesses of pinecones or other structures (for which a long and slender beak may facilitate access to those seeds) (Benkman 1993).

Similar patterns are also evident across species that exploit different food sources. Species that feed primarily or exclusively on small fruits (seed dispersers) tend to swallow those fruits whole, and those birds tend to have broader and flatter bills compared to other species (Herrera 2011). In contrast, species that feed on fruits only occasionally and rely on other food sources for most of their diet (seed predators) do not express those characteristics of bill shape (Herrera 2011). It is thought that the traits of beak morphology expressed by seed disperser species are advantageous in allowing them to feed primarily on fruit, whereas seed predator species do not express those specific adaptations and are therefore able to be dietary generalists that can exploit a greater range of dietary options.

Adaptations of bill morphology in association with diet and habitat are apparent even between closely related species. For example, long, flat bills are typical of birds that catch mobile prey, such as flying insects. In contrast, shorter, slightly curved bills are typical of birds that feed on more sedentary prey. In the case of warblers (Genus *Acrocephalus*), mobile prey are more abundant in marsh habitats, and the species of warblers that inhabit those areas tend to have long, flat bills. In contrast, less mobile prey are common in vegetation and undergrowth, and species of warblers that inhabit those areas tend to have shorter, slightly curved bills (Leisler et al. 1989). In perhaps the most compelling evidence in

support of the idea that beak size and ecological opportunities are related, a correlation between changes in beak size and changes in habitat is evident within the seasonal transitions of an individual species. Within honeyeaters (Genus *Meliphagidae*), beak size increases during the summer months, becoming more elongated during a time when those birds also increase their reliance on nectar as a food source (Friedman et al. 2019).

Beak morphology is also related to activities other than feeding, such as thermoregulation, singing, and preening behaviors. Beaks are a primary means through which birds release heat into the environment; thus, smaller or larger beaks have consequences for not only feeding and the acquisition of energy but also thermoregulation and the release of energy (Friedman et al. 2019). A large bill might enable a species to fare better in a very warm climate than if it had a much smaller bill, opening the door to occupying a niche that the species might otherwise not inhabit. In singing, the beak is part of the vocal tract that influences the resonance of specific frequencies in calls or songs. If the beak is wide open, the overall vocal tract is shorter (favoring higher frequencies) than if the beak is more closed (favoring lower frequencies) (Huber and Podos 2006). This is similar to the musical phenomenon in which larger, longer tubes in a pipe organ produce lower notes than smaller, shorter tubes. Finally, beaks can also play an important role in the bird's ability to maintain its health through preening and removal of harmful parasites (Clayton et al. 2005). Thus, beaks can influence many aspects of a species' ability to thrive in different contexts, and demands and advantages such as these are thought to have acted as strong driving forces in shaping the evolution of beak morphology.

## Variability in the Pectoralis Muscle

Flight is a very metabolically expensive behavior, and different species of passerines express different traits in the powerful muscles that enable flight (Welch and Altshuler 2009). The pectoralis muscle is the dominant muscle associated with

powering flight as well as other aspects of survival such as thermoregulation by shivering, and it accounts for the majority of muscle mass in birds. Within the pectoralis, there can be different types of muscle fibers (e.g., DuBay et al. 2020). Some of those fibers can be glycolytic, meaning that they rely on cellular energy reserves such as glycogen that is immediately accessible. Other muscle fibers can be oxidative, meaning that they rely on oxygen obtained through respiration as their energy source. These differences can have functional consequences, as glycolytic fibers are excellent for producing rapid movements but they are more easily exhausted than oxidative fibers. Therefore, different composition of fibers in the pectoralis muscle may be better suited for different types of brief versus sustained behaviors.

Within the pectoralis of small-bodied birds, muscle fibers are often exclusively oxidative, whereas the pectoralis in larger species contain a much greater proportion of glycolytic fibers (Welch and Altshuler 2009). This is thought to reflect the different demands that species of different sizes face in takeoff and continued flapping during sustained flight. For example, large birds may be more dependent on the bursts of power that glycolytic fibers provide to lift them into the air. Interestingly, recent research has revealed that glycolytic fibers may be present in the pectoralis of small birds (DuBay et al. 2020). In most small species, the pectoralis is composed exclusively of oxidative fibers, and these new data suggest that species diversity in the composition of pectoralis fiber types may play important roles in not only powering takeoff but also other aspects of survival such as competitive interactions or predator avoidance (DuBay et al. 2020). In support of that idea, the proportion of glycolytic fibers is greater in socially dominant small birds than in less dominant members of the same species (DuBay et al. 2020). Together, these results reveal that diversity in pectoralis muscle fiber composition is evident not only across but also within passerine species. Those differences have functional consequences, and diversity may be influenced by not only evolutionary history but also experiences that accrue within an individual's lifetime.

## Variability in Hindlimb Morphology

Different habitats place different demands on their inhabitants. For example, flat environments typically require little or no climbing, but habitats with steeper or perhaps even vertical surfaces could require very different patterns of locomotion. These differences in demand may be evident as structural differences between species that have adapted to each type of location. For example, warblers (Genus *Acrocephalus*) that live in environments where they commonly cling to vertical surfaces have long backward-facing toes, while those that live in habitats where they commonly run along the ground have adapted to express a longer version of a different toe (Leisler et al. 1989). In another example, species that are more reliant on hopping behavior for predator avoidance and takeoff tend to have longer foot bones (tarsus) than species who do not rely on those behaviors (Swaddle and Lockwood 1998). Adaptations of the hindlimb are also evident in the muscles that control flexion of the joints in the leg and foot. Anatomical differences associated with greater maximal force of contraction and flexion are evident in species that are more reliant on hanging behavior for their perching and feeding, and it is thought that these adaptations are helpful in counteracting the effects of gravity (Moreno 1990).

## Variability in Wing Shape and Feather Size

Passerine species also vary in the shape and size of their wings, and those differences are thought to be associated with differences in behavior and habitat. In another example from warblers, species that exploit taller vegetation tend to have broader wings than those that move through shorter and more tangled vegetation (Leisler et al. 1989). It is thought that those differences are functionally significant because broader wings may facilitate takeoff from within tall vegetation, whereas more narrow wings may facilitate maneuverability through dense vegetation (Kennedy et al. 2020).

Studies of other passerine species have revealed that species with rounded wingtips as opposed to pointed wingtips are at a lower risk for predation, and it is thought that rounded wingtips may enhance flight performance at slow speeds and thus allow individuals to take off more quickly and at steeper angles than birds with sharper wingtips (Swaddle and Lockwood 1998). The properties of these different types of wingtip are associated with differences in the lengths of the primary and secondary flight feathers on the wings of those species. Thus, passerine species express diversity in the features of the structures that power and control flight, and those anatomical differences are closely correlated with differences in habitat.

### Variability in Behavior

In addition to anatomical differences between species, passerines also vary in their behavior. Some species have been characterized by the ability to learn the sounds they used in vocal communication (Suborder Passeri within the Order Passeriformes). These birds are commonly called “songbirds” or “oscines,” named from the Latin word for singing birds. The ability to learn the sounds used in communication is a feature of human communication through speech, but it is otherwise rare across animal species (reviewed in Martins and Boeckx 2020). Therefore, songbirds have been the focus of research into not only the ways that song is used by those species but also how it may be informative as a means of understanding how we communicate through speech. Vocal learning is associated with the presence of specialized structures in the songbird brain, and a growing body of research is providing insight into how studies of songbirds may help us understand the mechanisms of human communication (reviewed in Mooney et al. 2008). In addition to the songbirds that comprise Suborder Passeri, other passerines (Suborders Tyranni and Acanthisitti) have long been thought to have little or no reliance on learning in their acquisition and performance of the signals they use in

communication (e.g., Kroodsma 1984). That is reflected in the commonly used term “suboscines” to refer to those birds. However, recent research suggests that such a dismissive term may be inappropriate and that the differences between these groups are not as stark as was previously thought (reviewed in Martins and Boeckx 2020). Feedback-dependent effects on vocalizations are a hallmark of the vocal learning process, and suboscine species have been shown to modify their vocalizations based on sensory experience (Kroodsma et al. 2013; Martins and Boeckx 2020). The effects of experience on song performance are much greater in songbirds than the effects seen in suboscines, but research suggests that both groups may be at least somewhat dependent on learning in their vocal communication (Martins and Boeckx 2020). Thus, the difference between these groups may be one of degree rather than a categorical distinction. Ongoing research is seeking to understand these differences and their associated neural circuits more fully as a means of understanding how the brain enables perception and learning in not only these passerine species but also ourselves.

### Passerine Success across Many Different Niches

As noted throughout this entry, passerines comprise a large number of species that are quite diverse in their morphology, life history, and behavior. They have adapted to occupy a broad range of terrestrial habitats and a similarly diverse range of ecological niches. Their characteristics such as relatively small bodies, large brains, arboreal living, reproductive success, behavioral flexibility, and ability to feed on a broad diversity of food sources have apparently provided them with abilities to colonize new areas better than any other group of birds (Olalla-Tárraga et al. 2019). This tolerance and adaptability may also explain how they have been able to thrive across diverse and widespread habitats. Changes throughout Earth’s history may also have played a key role in their success, as global climate changed during

the Tertiary period and adaptive radiation among flowering plants and insects gave rise to a diversity of habitats that may have been especially well suited to support small birds (Oliveros et al. 2019).

Passerines also express many behaviors that are also thought to have helped them thrive throughout their history. For example, passerines have an extraordinary ability to create nests out of a wide range of materials, place them in a variety of areas, and conceal them effectively against threats from predators and the environment (Olson 2001). Those nests provide protection for not only the birds that construct them but also their offspring, and that is especially beneficial in light of how vulnerable hatchlings are during the earliest days of their lives. The ability of passerines to protect their young in this way may also have contributed to their success (Olson 2001). Additional aspects of reproduction such as rapid development to an early age of sexual maturity and the associated short generation times may have also contributed to successful adaptation to novel environments. Passerines are also behaviorally flexible and capable of complex learning, as shown by their mate choice strategies and vocal behavior. In addition, many species are capable of migrating over very long distances, enabling them to disperse over wide ranges and take advantage of resources present across those different locations (Olson 2001). Taken together, these features reveal that passerines express many anatomical and behavioral traits that have likely contributed to their ability to reach new environments, adapt to survive there, and evolve into the diversity of passerine species that we observe today.

## Passerine Navigation

Joseph F. Di Liberto

University of California, San Diego, CA, USA

## Definition

The methods in which birds of the order Passeriformes are able to orient themselves in regard to their geographic location, and then utilize this information to move toward a geolocational goal.

## Introduction

For thousands of years, humans have borne witness to the incredible navigational abilities of birds. The knowledge and utilization of these birds' abilities goes as far back as ancient Egypt, some 4000 years ago, where sources tell what humans learned about, and proceeded to utilize the homing abilities of domestic pigeons (*Columba livia* v. *domestica*) to carry urgent messages more quickly than human, or other animal couriers (Blechman 2007; Newton 2010). While technology in the past couple centuries has made the use of homing pigeons obsolete, interest in the scientific basis of avian navigation has conversely expanded as questions began to emerge regarding how all types of birds were able to so readily find their way home or successfully migrate across great distances. Considering the popularity of homing pigeons with humans, it was no wonder that early studies on overall avian navigation had focused mainly on members of the *Columbidae* family (Wiltschko and Wiltschko 2003). However, other studies sought to expand upon these early findings to examine navigation in a variety of bird taxonomic groups, most notably, the passerines.

The order of "perching birds" or Passeriformes comprises over half of all bird species diversity (59%, Sibley and Monroe 1990), and the incredibly precise nature and ability of these birds' navigation, particularly in migration, has been observed and analyzed since antiquity (Berthold et al. 2013). In passerines, as with many species of bird, accurate navigation and site fidelity are highly important for accruing fitness benefits – especially in birds that undergo the aforementioned migration as part of their life history (Newton 2010). This importance of navigational ability has made the subject of considerable interest among ornithologists in the past century, with a variety of studies using passerine models to examine different navigational mechanisms and theoretical concepts (Kramer 1952; Able and Able 1993; Cochran et al. 2004; Wiltschko and Wiltschko 2015).

While passerines such as the European Starling (*Sturna vulgaris*), European Robin (*Erithacus rubecula*), and Zebra Finch (*Taeniopygia guttata*)

have been the subject of studies that have provided foundational research into constructing the current understanding of avian navigation, many other important discoveries have used species within different orders – such as homing pigeons and seabirds – to test and form other crucial concepts (Wiltschko and Wiltschko 2003, 2015). However, given the lack of information on potential variation in individual bird species' navigational toolkits, it is generally accepted that most birds navigate by using the same core mechanisms (Wiltschko and Wiltschko 2003). To that end, findings in other avian taxa on the methods and mechanisms of navigation, particularly in regard to earlier, ubiquitous concepts, should be considered and applied when discussing passerine navigational systems.

## Early Studies and Frameworks on Orientation

Pioneering studies in avian, and by extension passerine, navigation utilized an inductive approach which mostly employed large-scale displacement experiments with goals of discovering maximum distances in which birds were able to home, and how various conditions could affect navigational performance (Wiltschko and Wiltschko 2003). While many of these foundational studies occurred in seabirds such as noddies and terns (Watson and Lashley 1915), other studies made use of free-living passerines such as starlings and swallows in their displacement studies (Rüppell 1935; Sargent 1962). Regardless of species, these early studies generally expressed the birds' superb homing abilities over considerably long distances from unfamiliar starting locations. Additionally, another study in seabirds reported that certain seabirds were able to successfully navigate across the open ocean, showing that avian navigation did not necessarily depend on the use of familiar landmarks: a then contemporary viewpoint that had been continually tested in homing pigeons to inconclusive results (Lack and Lockley 1938; Wiltschko and Wiltschko 2003). While these studies were able to further solidify the extent and ability of birds' homing and navigational ability, they were not able to concretely

suggest or show any factors or mechanisms behind this ability only concluding that the birds seemingly had a nebulous “sense of direction” or “sense of space.”

It was not until the middle of the twentieth century that much of the foundational knowledge on the theoretical and mechanistic factors of avian navigation was more thoroughly constructed. One of the most foundational and key concepts developed during this widening in navigational research was the three types of homing orientation first described by Donald Griffin. Having reviewed the literature on past navigational research, his classification, as detailed in Griffin (1952), was characterized by the apparent complexity of the exhibited navigational process. In Griffin’s classification, the most basic form orientation – referred to as Type I or “piloting” – was the birds’ directed search for familiar landmarks or features when displaced. Griffin argued that this was the simplest form of navigation among birds and that most birds in unfamiliar territory would utilize this orientation strategy. Building from piloting, the Type II orientation, later referred to as “one directional orientation,” suggested that birds would use a single directional cue and then proceed to navigate in that direction until a familiar landmark or area could induce piloting orientation (Griffin 1955). Finally, in Type III orientation, the bird would use some sophisticated and undiscovered mechanism to choose the approximate direction and path despite having no precursory direction or familiar landmarks in which to use. As a result, this final type of orientation has been known as “true navigation” and lay the foundation of other proposed mechanisms to thoroughly explain how birds were able to orient themselves (Wiltschko and Wiltschko 2003). Aligning with the “increasing complexity” that Griffin suggested in his three types of orientation, each type was based on an increasing number of references: Type I is largely independent of external references, Type II uses one factor as a reference, and Type III makes use of two external factors to create a more complete navigational compass (Adler 1970). While Griffin’s three types of orientation were criticized among ornithologists for their simplicity and disregard of wild bird motivation and ecology

(Keeton 1974), the descriptions successfully created the first classifications into avian orientation behavior and provided an ample conceptual framework for aligning upcoming discoveries in the mechanisms used in avian navigation.

## Sun Navigation and the “Map and Compass”

During this same period, a series of pioneering in passerines, namely starlings (*Sturgis vulgaris*), were able to determine that the sun is a directional cue used by birds in diurnal navigation (Kramer 1950). In these experiments, researchers trained captive starlings kept in circular cages to feed in a particular compass direction. With only the day-time sky above being visible to the starlings, results showed that the birds were able to maintain their trained feeding directions throughout the day. As the starlings were seemingly allowing for the changing position of the sun in their orientation, the birds must have needed to be keeping track of two different factors: a biological clock, and a knowledge of the sun’s movement (Kramer 1950; Schmidt-Koenig et al. 1991). This discovery was not only key in further unearthing upon the previously nebulous mechanisms of avian navigation, but also importantly allowed for this concept to play a central role in the “Map and Compass” model, a key model in which the current understanding of avian navigation is still largely rooted (Schmidt-Koenig et al. 1991; Wiltschko and Wiltschko 2003).

After discovering the sun compass, Gustav Kramer proposed his “Map and Compass” model in order to provide a theoretical framework to his findings. Kramer described avian navigation or goal orientation in a two-step process: First, the bird determines its goal direction as a compass course, and second, it uses a compass mechanism to locate this course (Kramer 1953). Alternatively stated, the first “map” step allows the bird to find a specific direction – equivalent to humans’ use of cardinal directions – in which its goal is, while in the second “compass” step, this course is converted into a direction of flight. Kramer’s model was able to solidify that compass orientation was a vital aspect of avian goal

orientation, and its subsequent adoption has made navigation researchers compartmentalize their findings in terms of how any experimental manipulation affects either the map or compass step (Wiltschko and Wiltschko 2003).

While Kramer's model had naturally been able to use sun navigation as birds' compass mechanism, it was not able to propose anything for the map step leaving it largely open for future studies. Researchers proceeded to develop two main ideas for maps in order to fill this gap in the model: the grid and the mosaic (Wallraff 1974). The grid map suggested that birds would be able to sense differences in two different kinds of environmental gradients that are in continual change. Using this system as a map, birds would then be able to use a compass mechanism, such as the aforementioned sun compass, to pinpoint differences in scaled values at their present location to remembered values at their goal or home location. While the grid map is highly useful in picking up on more dynamic changes in geolocation, it falters when considering how birds are accurately able to find a target or home within an area of largely similar environmental gradients. As localized navigation has been long known to be predominantly based on visual cues and landmarks, the mosaic model accounts for this by combining mapping mechanisms (Deutschlander and Beason 2014; Wallraff 1974). Thus, in the mosaic model, the map is built as a mental representation of the distribution of known landmarks in the home area combined with the compass-accrued directions from these landmarks to home or other spots of interest (Wiltschko and Wiltschko 2015). Both the grid and mosaic maps indicate the direction to the goal as being a compass course (Wiltschko and Wiltschko 2003).

## Other Compass Mechanisms

While Kramer's work with the sun compass was sufficient in showing how birds were navigating during the day, it left open the question of how birds could navigate in nonclear skies, and nocturnally (Kramer 1950, 1953). This was of particular interest for many species of passerines that migrate nocturnally and thus could not be utilizing

a sun compass (Deutschlander and Beason 2014). One of the first and most widely accepted compass mechanisms to be proposed was a magnetic compass. Through controlled manipulation experiments of birds' magnetic field, researchers were able to show that migratory passerines such as the European Robin (*Erithacus rubecula*) and Savannah Sparrow (*Passerculus sandwichensis*) could have their orientation disrupted, demonstrating a robust ability for magnetic orientation (Wiltschko 1968; Able and Able 1993). To this effect, an inclination for a magnetic compass has been found in all species of bird tested, regardless of order or migratory status (Wiltschko and Wiltschko 2015).

Beyond the magnetic compass, other potential sources of compass information have been proposed and tested in passerines – most of which have been related to celestial aspects for navigation. Multiple species of migratory passerines have been tested to have been able to detect and utilize levels of polarized skylight available in dusk skies (Able 1989). Additionally, stellar patterns have been tested to be an adequate compass for nocturnal migrants such as Indigo Buntings (*Passerina cyanea*) and Blackpoll Warblers (*Dendroica striata*), providing another usable compass mechanism for nocturnal migrants (Emlen 1967; Emlen 1975). With any of these alternate compass mechanisms, birds accrue essentially the same directional information as the sun compass, meaning that any of these mechanisms can be substituted for the compass step in Kramer's model without issue.

## Compass Mechanism Interactions

Given that multiple types of compass mechanisms exist, questions arose regarding the relative importance of these mechanisms to each other. For many years, the role of the magnetic compass was thought of to be just a backup method to be used in unclear or nighttime skies, retaining Kramer's sun compass as the primary mode of gaining directional information (Wiltschko and Wiltschko 2003). After a series "cue-conflict" experiments in which birds were tested in situations where different compasses would provide

contrasting information, it has been generally accepted that birds' compass mechanisms should not be thought of as independent sources of directional information. Rather, the plethora of experiments that have studied the interaction of these magnetic and celestial compasses suggest that these mechanisms should be thought of as different components of a system complex for orientation and navigation (Åkesson 1994; Wiltschko and Wiltschko 2015). While some studies have described this interaction as a compromise between these magnetic and celestial compass systems (Åkesson 1994), others have shown clearer preferences for compass mechanism based on the life history of the bird species. Generally, both nocturnal and diurnal migrant passerines tend to rely more heavily on the magnetic compass with the sun compass playing only a minor role (Åkesson et al. 2006; Bingman and Wiltschko 1988). This contrasts with studies in nonmigratory, diurnal pigeons that seem to have indicated a preference in these birds using the sun compass, only switching to the magnetic compass upon the perceived failure of the sun compass (Wiltschko and Wiltschko 2015). While preferences in compass mechanism may exist between species, these same cue-conflict studies have also readily shown a willingness in birds to adapt by either using a different compass, or by using other compass mechanisms such as polarized light to "recalibrate" their preferred compass (Deutschlander and Beason 2014; Wiltschko and Wiltschko 2015; Cochran et al. 2004). Overall, while the multiple different compass mechanisms used in navigation may be used at different frequencies or may interact with each other, they regardless work together to form a complex, integrative system that allows birds to detect and utilize crucial directional information – even when one particular mechanism is compromised – throughout their course.

## Conclusion

The field of passerine navigation is a continually evolving subfield of avian navigation that is only expected to become more refined and integrative in the future. As the core theoretical framework and mechanisms used in passerine navigation are

highly analogous to that of many other avian species, recent years have seen an increasing number of passerines become focal species in navigational or homing research. And while some of these studies have just sought to better refine concepts in avian navigation collectively, they have also importantly assisted in drawing attention to observed differences in the passerines' navigational behavior and abilities as well. In particular, use of migrant passerines has been and continues to be a major area of study as advances in tracking technology have allowed for less invasive and more comprehensive work on navigation during seasonal migration. Additionally, an interdisciplinary approach to passerine navigation using neurobiological and cognitive techniques has also gained traction to better explain how navigational information is processed in birds' brains, and to gain further insights on passerines' navigational development and ontogeny (Wiltschko and Wiltschko 2015). In utilizing these and other avenues of research, further navigational studies in passerines may not only expand the body of knowledge within this particular taxon, but also importantly continue in contributing to the advancement of avian navigation as a whole.

## Passerine Sensory Systems

Cristián Gutiérrez-Ibáñez

Neuroscience and Mental Health Institute,  
University of Alberta, Edmonton, AB, Canada

### Definition

A passerine is a bird that belongs to the order Passeriformes. This order has over 5,000 identified species, which makes up more than half of all bird species. The order is divided into three suborders: Tyranni (suboscines), Passeri (oscines), and the basal Acanthisitti.

Sensory systems are the peripheral neural structures where sensory transduction and transmission of sensory activity to the central nervous system take place.

### Introduction

Oscines (from Latin *oscen*, “songbird”) are the largest group of passerines, and they owe their name to their complex vocalizations, or songs, which they learn by imitating their conspecifics (in some cases heterospecifics, e.g., mocking birds *Mimus polyglottos*). Songbirds have received a great deal of attention from

neuroethologists and neuroscientists because they are one of the few vertebrate models of vocal learning. However, most studies in avian sensory systems have focused in nonpasserine birds, like pigeons and chickens as general avian models for neuroanatomy and physiology, or in sensory specialists like the barn owl for sound localization. Nonetheless, there is a growing amount of research on the sensory systems of passerines, driven in part by the great ecological and behavioral diversity found in this group, which offers the opportunity to study how sensory system evolves in response to changes in these parameters.

### Vision

Vision has been largely regarded as one of the most important senses in birds. This is likely true in passerines as well. Passerines rely on their visual system to evaluate predation threats, navigate, avoid obstacles, recognize conspecifics, and forage. The first stage of visual processing occurs in the retina, where photoreceptors detect individual photons of the light that make up the image and produce electrical signals that reach the retinal ganglion cells (RGCs) through a complex circuitry involving many other cell types. In turn, the RGCs send their axons to the primary visual centers of the brain. Birds have three kinds of photoreceptors, rods, cones, and double cones, the latter consisting of structurally and functionally integrated pairs of cones. Rods are responsive at low light levels, while cones are responsive at high light levels. Different photoreceptors contain different photopigments called opsins, which are sensitive to different parts of the light spectrum or, more simply put, respond to different wavelengths of light. In passerines, as in other birds, rods contain only one type of photopigment which is most sensitive to light around 500 nm ( $\lambda$ -max of 500 nm), while different cones can contain one of the four types of photopigments, including a short-wavelength, ultraviolet (UV)-violet light-sensitive cone. In contrast, humans have cones with only three types of photopigments, none of which are sensitive to UV-violet light. There is evidence that all four cone types in birds are involved in color vision, and therefore passerines

(and most bird and reptiles) can be considered as having a tetrachromatic visual system, in contrast to a trichromatic in humans and a dichromatic in most mammals. All passerines are sensitive to UV light, but there is a pronounced difference among different clades in the wavelength of peak absorbance ( $\lambda$ -max) of the opsin in the UV-violet cone (first shortwave-sensitive opsin, SWS1). Thus, two types of tetrachromatic vision exist among passerines: a UV-sensitive (UVS), with a SWS1  $\lambda$ -max absorbance of 355–380 nm and a violet-sensitive type (VS), with a SWS1  $\lambda$ -max of 402–426 nm (Ödeen et al. 2011). So far, evidence suggests that all species within the large clade of the Passerida (which includes thrush-, sparrow-, and warbler-like passerines) present a UVS type. Among other passerines, the VS type dominates, although transitions to UVs have occurred many times independently. Some groups show consistency in their color vision type, such as corvids and subocines, which all present VS vision. In contrast, the family Maluridae (fairy wrens and allies) shows several shifts between UV and UVS vision. In all, passerines present at least eight shifts between UV and UVS vision, and the ancestral condition among passerines is unknown. Parrots (Psittaciformes), the sister group of passerines, have UVS-type cones, which suggests that UVS vision might be the ancestral type. The sensitivity of the other cones varies less pronouncedly among passerines although there are some interspecific differences (Hart et al. 2000). The  $\lambda$ -max of the other cone photopigments is around 470 nm for the shortwave type II opsin (SWS2), 505 nm for the rhodopsin type II (RH2), and 565 nm for the long wave-sensitive (LWS) opsin. In addition to the different types of photopigments, passerine cones (as in other birds and reptiles) each have an oil droplet in the proximal part of their outer segment. These oil droplets contain different carotenoid-based pigments and have the function of filtering light before it reaches the photopigments of the cone. This sharpens the spectral tuning of the receptor and thus reduces the overlap with adjacent spectral classes of cone. Further, oil droplets shift the peak sensitivity of each cone toward longer wavelengths (Hart and Vorobyev 2005).

In addition to the variation in spectrum sensitivity of some photopigments between different species, image analysis in the retina is also influenced by variation in the amount and distribution of both photoreceptors and RGCs. Variation on the distribution of different cones in the retina means that different parts of the retina could have different spectral sensitivities. This type of variation has been shown in several groups of birds, including Passeriformes, but has not been studied in many species and is not completely clear what its function is. Many more studies have shown different patterns of distribution of RGCs in the retina of Passeriformes and other birds. These patterns can be, for example, circular, with a very high concentration of RGCs at the center and a gradual decline of RGC density away from the center of the retina. In some species, more than one high-density area occurs, while in others a linear band or streak of high density of RGCs occurs. Areas of very high density of RGCs can be associated with the presence of a fovea, in which the outer layer of the retina is displaced to form a small pit or depression on the surface. The usual interpretation is that these areas of high RGCs density represent areas of enhanced spatial resolution. This means that different parts of the retina, and therefore the visual field, have better or worst visual acuity. The more common explanation for the differences in distribution of RGCs among different species of birds, including Passeriformes, is that they relate to differences in either foraging (the detection of food items in the frontal or lateral field of view) or the detection of predators (Moore et al. 2015).

Finally, there is also variation in the visual field of different Passeriformes. Most passerines have laterally placed eyes; however, the amount of overlap between the visual fields of both eyes and the blind spot behind the head vary between species. It is worth noting that passerines can have wide ranges of eye movements (with both eyes  $>60^\circ$  across all elevations), so visual fields can vary greatly. Variation in the size of binocular overlap, blind spots, and range of eye movements has been proposed to also correlate with foraging strategies and antipredatory behaviors (Moore et al. 2015).

## Hearing

Most passerines, particularly oscines, can be considered auditory specialists, bearing in mind the central role that vocalizations play in their social interactions. Nevertheless, hearing organs and their capabilities differ little from other birds.

Detection of sound waves is achieved in birds, reptiles, and mammals by the ear which consists of three parts: the outer, middle, and inner ear. In birds, the outer ear usually consists of a simple tube with its entrance located behind the eye. In passerines (and other birds), this is usually covered by small feathers. At the end of the outer ear is the ear drum, which separates the outer ear from the middle ear, and consists of the tympanic membrane, a thin membrane that acts as the first step in sound detection as it oscillates with the pressure oscillation produced by sound waves. Birds, like other land vertebrates, cannot respond directly to these vibrations as their inner ear, where the receptor resides, is filled with liquid. The middle ear acts as a transducer between the two mediums, the air in the outer ear and the liquid in the inner, such that it makes the liquid vibrate at the same rate as that of the air. In birds, reptiles, and amphibians, this is accomplished by a single bone, the columella, which at one end connects to the ear drum and in the other to the oval window of the inner ear. In contrast, in mammals this is achieved by three interconnected bones. The receptors that detect the vibrations transmitted into the fluid of the inner ear are called hair cells. Hair cells are located in the basilar papilla. Body size and the length of the basilar papilla are positively correlated, while the most sensitive frequency in a given species is inversely related to the body size and the length of the basilar papilla (Gleich et al. 2005). Unlike mammals, birds (including passerines) can regenerate auditory hair cells in the basilar papilla after loss of original hair cells (Woolley et al. 2001).

The ability of passerines to localize sound in space is rather poor when compared to mammals and specialist birds like owls. In all vertebrates, localization of sound sources depends on interaural comparison of time of arrival and intensity of the sound. These parameters are known as

interaural time difference (ITD) and interaural level difference (ILD). Passerines have been shown to use both of these cues to detect sound sources in the horizontal plane (Klump 2000), although the small size of the head and therefore the small distance between the two ears of most passerines greatly restrict the maximum ITD and ILD that can be attained. These factors result in poor spatial resolution. Passerines can resolve azimuth with acuities of no more than  $20^\circ$  and in many cases worst, up to  $70^\circ$  (Klump et al. 1986; Nelson and Stoddard 1998); this compares to  $1\text{--}2^\circ$  of acuity seen in some species of owls (Knudsen et al. 1979). Passerines, like all other birds with the exception of some owl species, lack pinnae or any other external ear structure. This means that their ears or head offers no cues for detecting sounds in elevation, and therefore passerines have to use behavioral strategies, like tilting their heads or moving to a different location, to localize sounds in three dimensions (Dooling 1992; Klump 2000).

Hearing frequency ranges have been studied for many passerines species. In general, these span from 100 Hz to 10 kHz, although hearing sensitivity rapidly deteriorates above 7 kHz and maximum sensitivity is usually below 4 kHz. Overall, hearing ranges of passerines are higher than those of nonpasserines (excluding owls). For example, a comparison of behaviorally determined audiograms showed that nonpasserines (8 species) have in average a lower maximum audible frequency (7.5 kHz) than passerines (9.7 kHz, 13 species) and also that nonpasserines have a lowest peak frequency sensitivity (2.1 kHz) than passerines (2.9 kHz; Dooling 1992). Among passerines, there is a strong correlation between the frequency of peak hearing sensitivity and specific spectral features of song (Dooling and Fay 2000). Although some species of passerines produce harmonics of their songs into ultrasound frequencies ( $>20$  kHz; Narins et al. 2004), there is no evidence of ultrasound hearing in any passerine (or any other bird). Infrasound detection ( $>25$  kHz) has been shown in pigeons and chickens but not in passerines so far, although it has not been systematically studied.

The clearest role of hearing in Passeriformes, particularly in oscines, is directly related to their complex vocalizations. Both learned and non-learned vocalizations are used in this group for all kinds of social interactions, such as begging, conspecific recognition, courtship, territorial displays, and alarm calls. Hearing in passerines also has been shown to be important in detecting predators. Therefore, hearing plays a central role in the behavior of these birds.

### Somesthetic Senses

The somesthetic senses, which include touch (mechanoreception), temperature, proprioception, and pain, have not been specifically studied in songbirds to a great extent and therefore much has to be drawn from general knowledge in other species, mostly the domestic chicken and pigeons. Passerines are not considered somatosensory specialist as they do not rely heavily on somatosensory information for feeding like other birds, namely, waterfowls, beak-probing birds (e.g., some shorebirds, ibises), and parrots, which use somatosensory information from their beaks and tongues to detect and/or manipulate food (Gutiérrez-Ibáñez et al. 2009). Nonetheless, somatosensation without a doubt plays an important role in many aspects of passerines behavior.

Mechanoreceptors respond to movement of objects or liquids that are in direct contact with them. Different types of mechanoreceptors respond to different properties of movement: vibration, velocity, and amplitude (Gottschaldt 1985). The most common mechanoreceptors in the integument of passerines are the encapsulated Herbst corpuscles, which respond to vibration and are similar to the mammalian Pacinian corpuscles. These sensory endings are located in almost all the body but vary in morphology depending on the location. Herbst corpuscles can be found in the beak, skin, tendons, muscle, joint capsules, and at the base of feather follicles. In grain-feeding Passeriformes, particularly finches, Herbst corpuscles are located in places of the bill which are mechanically involved in seed opening (Martin 2017), as well as in the tongue mechanosensory papillae (Wild 1990). The association of Herbst corpuscles to feather follicles is thought to be

important for providing birds with information about air speed and movements during flight. Some of the first evidence for this comes from studies in Passeriformes (Gewecke and Woike 1978). The bristle feathers, stiff feathers that grow in the face and at the base of the beak of birds (including many passerines), are associated with numerous Herbst corpuscles, suggesting that they constitute tactile specializations (Cunningham et al. 2011). Another type of mechanoreceptor in birds is the Grandry corpuscles, which detect the velocity component of mechanical stimuli and are most common in the beaks of somatosensory specialist birds. However, these receptors have also been found in the beak and skin of Passeriformes, usually near Herbst corpuscles. Little is known about temperature receptors in birds in general and even though these have been detected in a few species (e.g., waterfowls and chickens), they are likely widespread among birds, including passerines. Pain perception has been almost exclusively studied in domestic chickens but is also without a doubt common to all birds. The avian nociceptors are likely very similar to those of mammals.

### Magnetoreception

There is strong evidence that both passerine and nonpasserines birds can sense the earth's geomagnetic field and that this sense is used as a compass for orientation (Wiltschko and Wiltschko 2006). Many behavioral experiments show that strong magnetic fields, which disrupt the weak magnetic field from earth, abolish orientation behavior in birds, including passerines (Wiltschko and Wiltschko 2006). After some controversy, it is now more or less accepted that birds detect magnetic fields through two different mechanisms and that both are likely present in the same individuals. These mechanisms are known as the "radical pair model" and the "magnetite model." The radical pair model proposes a chemical compass based on alterations caused by the magnetic field on a chemical reaction involving special photopigments in the retina and therefore that are detected by the eye. This model is supported

mainly by evidence that in migratory birds, especially passerines, magnetoreception is light-dependent. In classic experiments, passerines kept in captivity orientate themselves toward the direction of migration when the correspondent season arrives but only in the presence of light in the lower end of the spectrum, from blue to green. Birds kept in the dark or under red light do not orientate (Wiltschko et al. 2010). The magnetite model involves crystals of permanently magnetic material in the head. Deposits of iron oxides or magnetite have been found in different parts of the head and beak of birds, including migratory passerines (Beason and Nichols 1984). Also, there is evidence in passerines that changes in magnetic field result in activation of neurons in the brain regions that receive sensory projections from the beak (Heyers et al. 2010). In conclusion, there is good evidence that passerines (and other birds) can detect the earth's magnetic field in at least two different ways and are likely to use it for orientation, although there is still some debate regarding how and when is each system used for navigation and/or orientation.

### Olfaction

The significance of olfaction to ecology and behavior of birds has been historically underplayed to the point that early ornithologists discussed if birds were capable of olfaction at all. It is now clear that not only birds are certainly capable of olfaction but also that it plays an important role in many aspects of avian behavior, including that of Passeriformes. In all vertebrates, olfaction is mediated by sensory cells in the olfactory epithelium. Each of these cells expresses different olfactory receptors (ORs), which constitute the molecular basis of the sense of smell (Gaillard et al. 2004). The total amount of OR genes and the fraction of OR genes that are nonfunctional (i.e., pseudogenes) vary widely between vertebrate genomes, and both have been suggested to correlate positively with olfactory acuity (Niimura and Nei 2006). Birds have between 100 and 650 OR genes, which are lower than reptiles but higher than some species of fish

and comparable to some mammals. Among birds, passerines have some of the lowest amount of OR genes (~150 to 200), although the proportion of pseudogenes is similar to other birds (Steiger et al. 2008). The amount of OR genes correlates positively with the size of the olfactory bulb, the brain region that receives olfactory inputs from the olfactory epithelium. In accordance with the low amount of OR genes, passerines have one of the smallest olfactory bulbs among birds relative to brain size (Corfield et al. 2015). Despite this apparent reduction of the olfactory system in passerines, several species of this group have been shown to have odor detection thresholds comparable to rats and rabbits. More importantly, there is growing evidence for a role of olfaction in different behaviors of passerines. Passerines have been shown to use olfactory cues for the detection of predators, navigation during migration, kin recognition, conspecific recognition, advertisement and mate selection, nest material preference, and foraging by insectivorous passerine birds.

### Taste

Taste has not been studied widely in birds in general, and much less in passerines, but something can be inferred from what is known for nonpasserine birds, mostly the domestic chicken and ducks. It is thought that birds in general have poor taste acuity compared to mammals due to their relative low saliva secretion, number of taste buds, and lack of mastication (Berkhoudt 1985). Nonetheless, it is clear that taste is as important to birds as it is to mammals. In birds, taste is involved in detecting both nutritious compounds, like amino acids, lipids, salts, carbohydrates, and calcium, as well as toxic compounds. Like in all vertebrates, taste signals in birds are generated in the taste buds. These are groups of cells, barrel or flask shaped, embedded in the tongue or oral cavity. In birds, taste buds are found not only in the tongue but also in the palate and other parts of the oral cavity. Unlike most mammals, bird species examined so far have very few or are missing altogether taste papillae and taste buds in the dorsal surface of the tongue. Recent studies

suggest that the number of taste buds in birds is similar to that of mammals in relation to the size of the oral cavity. Both behavioral and genetic evidence show that birds are responsive to several taste categories: sweet, umami, bitter, salt, sour, fat, and calcium. In the case of sweet, omnivorous and granivorous birds do not respond positively to sugars, although nectivorous and frugivorous species do, including the common starling, a passerine (Roura et al. 2013). Genetic analyses have shown that chickens do not possess an ortholog gene (i.e., inherited from a shared ancestor) to the human T1R2 gene (the sweet receptor). On the other hand, in hummingbirds the umami receptor has suffered several changes in its amino acid sequence to allow for the detection of sugars. It is not clear if this is also true for other nectivorous and fructivorous species of birds, including the many passerines with this kind of diet. Umami is generally identified as the taste of monosodium glutamate, and its function is interpreted as being the detection of amino acids or proteins. In birds there is a functional umami receptor gene, and some species of passerines, like the common starling and the red-winged blackbird (*Agelaius phoeniceus*), show preference for amino acids (Werner et al. 2008). Bitter compounds are usually associated with toxic compounds. Bitter receptors are also present in birds, and like in other vertebrates, they produce an aversive response, including in passerines like the common starling and the red-winged blackbird. Although information about other taste categories is scarce, the gene for sourness, that is for the detection of the presence of acids, is present in the genome of the chicken (Roura et al. 2013). Also, birds have the need for intake of salt (sodium chloride, NaCl) and calcium, and therefore it is likely that some receptors are involved in detecting these compounds in passerines and birds in general.

### Conclusion

While passerines can hardly be considered sensory specialist, their great diversity in foraging

strategies, habitat, and ecology provides unique opportunities to study the evolution of sensory systems. A good example of this is the increasing literature on the visual system of passerines. Evidence on the use of olfaction by passerines in different contexts is also ever-increasing and is likely to encourage further research on the physiology and anatomy of the olfactory system of passerines and birds in general. Much of our knowledge about hearing and magnetoreception in birds comes from passerines, but there is still much to be explored, particularly how the different forms of magnetoreception are used. On the other hand, little is known about the somesthetic senses or the sense of taste in passerines and birds in general.

## Definition

Birds of the order Passeriformes, known as passerines, include over half of the almost 10,000 known bird species (Mayr 1946). In comparison to other orders under the class Aves, passerines have a particular toe arrangement: three toes pointing forward and one pointing back (Proctor and Lynch 1993). This particular arrangement aids in perching, which has lead to the name “perching bird”.

## Introduction

Passerines include many songbirds, a group of more than 5,000 species that engage in vocal learning, similar to how humans, cetaceans, bats, elephants, parrots, and hummingbirds learn their vocalizations (Doupe and Kuhl 1999). Passerines, in general, are commonly referred to as songbirds, but this is not entirely correct. The order can instead be broken down into the Oscines and the Suboscines. Oscines (i.e., songbirds or “true” songbirds) have highly developed song and learn their species-typical vocalizations via a model (e.g., a parent) and have dedicated brain architecture. Suboscines, however, do not require a model to learn their species-typical vocalizations and continue to produce and perceive vocalizations even with damaged auditory brain regions; however, some species do have a rudimentary vocal system, the structure(s) within the brain

associated with production of vocalizations, which appears to act in the same way as in the Oscines (Kroodsma and Konishi 1991). These structures include rudimentary forms of structures like the robust nucleus of the arcopallium, which could indicate an evolutionary predecessor to a true vocal control system (see more details below; Liu et al. 2013). In North America, there is only one family of Suboscines: Tyrannidae, which includes flycatchers, phoebes, and king birds. Passerines primarily communicate using vocalizations, as acoustic signals are difficult to localize (e.g., in the presence of a predator), can travel across greater distances than visual cues, and are advantageous in dense vegetation. Passerines include a wide range of species found in both temperate and tropical climates.

## Passerine Species

### Example Temperate Species

Temperate forests extend north from the Tropic of Cancer to the Arctic Circle and south from the Tropic of Capricorn to the Antarctic Circle. The Paridae family includes the tits, chickadees, and nuthatches. Titmice are widely distributed and can be found in North America (e.g., tufted titmouse, *Baeolophus bicolor*), Africa (e.g., African blue tit, *Cyanistes teneriffae*), Asia and Europe (e.g., Great tit, *Parus major*). Chickadees are a group of North American songbirds including seven different species: black-capped (*Poecile atricapillus*), mountain (*P. gambeli*), Carolina (*P. carolinensis*), Boreal (*P. hudsonicus*), chestnut-backed (*P. rufescens*), Mexican (*P. sclateri*), and gray-headed (or “Siberian tit”; *P. cinctus*). Nuthatches mostly reside in North America (e.g., red-breasted, *Sitta canadensis*), but few species live in Eurasia (e.g., Eurasian nuthatch, *S. europaea*). A few examples of common non-Paridae temperate species include cowbirds (*Molothrus*), jays (*Corvidae*), sparrows (*Passer*), thrush (*Turdidae*), warblers (*Sylvia*), and wrens (*Troglodytidae*; Cornell Lab of Ornithology n.d.).

### Example Tropical Species

Passerines living between the Tropic of Cancer and the Tropic of Capricorn are classified as tropical

species. A few examples of these birds are the Andean cock-of-the-rock (*Rupicola peruvianus*), Wilson’s bird-of-paradise (*Cicinnurus respublica*), Australia’s regent bowerbird (*Sericulus chrysocephalus*), and multiple species of broadbill (*Eurylaimidae*). There are also multiple species of finches, such as the cut throat finch (*Amadina fasciata*), the Gouldian finch (*Erythrura gouldiae*), and the subfamily of Hawaiian honeycreepers (*Carduelinae*; Cornell Lab of Ornithology n.d.).

Zebra finches (*Taeniopygia guttata*) whose range extends from Eastern Indonesia throughout the arid regions of Australia, however, have such a large habitat that they cannot be considered only temperate or tropical. Zebra finches are one of the most widely studied bird species in avian neurobiology because they learn and memorize their song from a tutor bird, and this learning and memory process is similar to how human infants acquire language (Konishi 1985).

### Vocalization Types

Bird calls are often distinguished from song by a variety of characteristics, although in some species this distinction may be somewhat blurred. Songs are usually multipart sounds produced primarily by males during the breeding season as acoustic ornaments (Marler 2004; Smith 1991). Songs are used for the purposes of reproduction and territoriality, are typically produced in a consistent manner, and primarily by males in many species. In comparison, calls are typically simpler (sometimes even monosyllabic), produced by both sexes in all age groups, and used daily for the purposes of communication. Thus, calls serve a variety of functions crucial for survival (Marler 2004).

**Song** Songs are elaborate and complex vocalizations that have two main purposes: (1) to advertise and defend territory from other males and (2) to attract potential females for mating and potentially stimulate female reproductive behavior and physiology (Kroodsma and Miller 1996). The acoustic structure of birdsong is fairly consistent in production, which encompasses the notes, syllables, and phrases, and also dictates the way in which songs and song repertoires are delivered

(Marler 2004). Song repertoires can range in size from one simple song (as seen in the black-capped chickadee) to over a thousand complicated songs (as seen in the brown thrasher) (Kroodsma and Miller 1996). In order for birdsong to be acquired there has to be a predisposition to learning as well as being exposed to song (Brainard and Doupe 2002). Again, the learning process is generally divided into two phases, the sensory phase and the sensorimotor phase, which can overlap. During the sensory period, the songbird is in a sensitive state where the brain is prepared to receive auditory input. The songbird listens to the songs produced by adult songbirds (i.e., tutor birds) and their brain processes this auditory input, forming a memory template of song (Mooney 1999). This input leads to both neural and behavioral changes, which is followed by the sensorimotor phase. In this phase, songbirds start to produce their own song based on the template that was formed or activated during the sensory phase. Initially, this song is fairly inaccurate and variable and is often compared to babbling in human infants (e.g., Marler 1970). The auditory feedback that the songbird receives allows them to assess their performance and make changes until the song they produce matches the song template they developed during the sensory phase (e.g., Konishi 1965).

These early life experiences are crucial for song learning, and this learning can be disrupted in a variety of ways. The length of exposure to a tutor bird can drastically affect birdsong (i.e., shorter exposures lead to less complex song structures; e.g., Thorpe 1958). Acoustically isolating a bird from others during the sensory phase can lead to songs that are simpler, shifted in their frequencies, and extremely variable (e.g., Shackleton and Ratcliffe 1993). Preventing auditory feedback during the sensorimotor phase by deafening birds can also negatively impact song by producing shorter songs, delaying singing behavior, or even eliminating song altogether (e.g., Konishi 1965). However, many species still maintain some of the features of their species typical songs, indicating that there is partial encoding of some song features or an inherent song template that initially directs song learning (e.g., Bolhuis and Gahr 2006).

**Calls** Birds must maintain their social groupings, whether it is in the context of a mated pair, flock, or family group. Most birds have some form of contact call, which allows them to remain in contact with one another during foraging. Separation calls may be a variation of a contact call and are produced when a bird loses contact with its group. Finding food is also crucial for a bird's survival; therefore, some birds emit food calls which announce the presence of a food source enticing other birds in the group to come feed. A subset of these calls, begging calls, is produced by chicks after hatching which coax parents into feeding their offspring. These calls often allow for nest or kin recognition by the parents, or for nest mates to recognize one another (e.g., Beecher 1982).

Aggressive calls are used in antagonistic interactions between individuals, whereas alarm calls are used to announce the presence of a predator or danger in the environment (e.g., distress and mobbing calls). Distress calls are typically produced when the individual is in the grips of a predator (e.g., Zachau and Freeberg 2012). Conversely, when a nearby predator is detected, mobbing calls are used to attract other members of the group to harass or "mob" the predator in order to scare them off. There are also variations of mobbing calls that tend to code for the type of predator or the threat level posed to the individual (e.g., Templeton et al. 2005).

Calls were long believed to be innate; however, this is not the case for all species. Many calls are learned or partially learned (for review see Marler and Slabbekoorn 2004). Learning calls, as with songs, is also accomplished through a process of vocal imitation (Vicario 2004). Unlike songs that are produced primarily during the breeding season, many calls are produced year round and are more easily elicited in laboratory conditions. Again, the male zebra finch distance call, like their song, is learned from a tutor bird, and, as such, the calls vary between individuals (Simpson and Vicario 1990, 1991). Also, many calls are produced by both sexes, unlike song which is primarily produced by males. This allows researchers to examine the learning and development of calls in both males and females. There is

some evidence suggesting that the black-capped chickadee's namesake *chick-a-dee* call is partially learned (e.g., Hughes et al. 1998). Black-capped chickadees raised in social and acoustic isolation produce *chick-a-dee* calls; however, the quality of these vocalizations is poor in comparison to chickadees raised with a tutor (Hughes et al. 1998). Overall, this indicates that there is some evidence for learning calls in songbirds.

Unlike production of the *chick-a-dee* call, the ability to memorize, categorize, and discriminate *chick-a-dee* calls may not be learned. Whether or not birds were raised with their own species, they are able to discriminate between a foreign and familiar species typical *chick-a-dee* calls. Specifically, it appears as though chickadees' internal template for discrimination does not require input from adults within their own species (Bloomfield et al. 2008). Therefore, memorization and discrimination of the *chick-a-dee* call is not learned, but production seems to be partially learned.

## Structures and Perception

Oscines are characterized by a specialized and embellished (compared to Suboscines, see below) sound-producing organ, the syrinx. The syrinx is complex, comprised of five pairs of muscles, and is located at the junction of two bronchi, which allows for each bronchus to act as its own independent sound source. Vocal production is therefore accomplished by a complex interplay between muscle movements in the syrinx, air flow, and beak articulation. Suboscine species also possess a syrinx; however, its role in song production is unclear; song production and frequency modulation do not seem to rely entirely on the syrinx, but primarily on air sac pressure modulation (Amador et al. 2008). Oscines also possess a set of discrete brain nuclei called the vocal control system that are specialized for the acquisition, production, and perception of vocalizations. HVC (proper name, previously referred to as the high vocal center) and the robust nucleus of the arcopallium (RA) are integral components of the vocal control system within the brain of

Oscines, and we know that lesioning these structures can drastically impact song production (Nottebohm et al. 1976). It also appears as though these two structures may be involved in call learning and production. Lesioning HVC and RA in male zebra finches causes one of their vocalizations, the distance call, to become more female-like, and lose their male-typical characteristics (Simpson and Vicario 1990). Certain manipulations can cause females to be able to learn and produce male-like distance calls, such as estrogen treatment during development (Simpson and Vicario 1991). Early life exposure to estradiol causes a masculinization of vocal behavior in zebra finches; estradiol-treated females produce song-like vocalizations in adulthood, as well as being able to produce the male-typical aspects of the distance call. Eastern phoebes (*Sayornis phoebe*), a suboscine species, also possess a rudimentary RA-like structure (Liu et al. 2013). Since suboscine species, like the eastern phoebe, do not learn their song, this suggests that vocal learning may be an evolved trait.

Humans can hear sounds in the range of 20 Hz to 20,000 Hz, but best perceive sounds between 2,000 and 4,000 Hz (Dooling 1982). In comparison, birds have a more restricted hearing range, especially for higher frequencies where they do not detect sounds above 10,000 Hz (Dooling et al. 2000). Similar to humans, birds hear best between 2,000 and 5,000 Hz, with songbirds (i.e., Oscines) typically more sensitive to higher frequencies and non-songbirds typically more sensitive to lower frequencies within this range. Human perception thresholds tend to be lower than birds for all frequencies, meaning that birds can detect quieter sounds, but there are a number of exceptions, including many owl species. Although birds have a more narrow overall frequency perceptual range than humans, birds are more sensitive to absolute frequency, changes in frequency, and timing between sounds, which aid in perceiving and discriminating their own, and other species, complex vocalizations (Dooling 1982).

Even though birds and mammals are not closely related, the ears of both share a number of structural similarities (e.g., they both have inner

and middle ear structures, though the avian ear lacks a pinna or outer ear). In all vertebrate species, the middle ear serves to mediate the transfer of sound from the environment to the inner ear, usually by way of tympanic membrane vibrations and movement of a varying number of small bones. The avian middle ear has little variation among species and takes up a large amount of space relative to head size compared to reptiles and mammals. Avian ears have a single bone, the columella, while mammalian ears have three bones, collectively called ossicles. The mammalian cochlea is longer and coiled, while the avian equivalent, the papilla, is shorter and straight or slightly curved (Dooling et al. 2000). Both cochlea and papilla have specialized hair cells which vibrate in response to sounds of specific frequencies. However, the avian tall and short hair cells serve the same function as, but are not evolutionarily related to, the inner and outer hair cells in the mammalian cochlea. The orientations of these hair cells are fixed across mammalian species, but vary widely in avian species. Vibrations in hair cells are transferred to neurons, and certain hair cells are responsive to certain frequencies. Frequency and intensity are stored and passed into the auditory nerve. The pathway from auditory nuclei through the auditory areas of the brain is conserved across both birds and reptiles. From the auditory nerves, sound information projects to two cochlear nuclei which in turn project onto parallel pathways of auditory nuclei, one of which encodes information about sound loudness and the other which encodes timing. This auditory information eventually reaches Field L, which is involved in auditory processing. In songbirds, Field L projects to HVC and the RA in the vocal control system, allowing for recognition of and response to vocalizations (Dooling et al. 2000).

## Vocal Production

### Vocal Learning

Songbirds acquire some of their species-specific vocalizations through vocal learning; thus,

songbirds must attend to the vocalizations of others and modify their own vocalizations to match these models. Vocal learning is thought to be relatively rare in the animal kingdom, but has been documented in a number of vertebrates (Doupe and Kuhl 1999). However, to our knowledge Suboscines have not shown evidence of vocal learning.

Songbirds can generally be separated into two broad groups based on how they learn their vocalizations: open-ended and closed-ended learners (Brainard and Doupe 2002). Open-ended learners pass through a sensory phase in which they are sensitive to the auditory input they receive and acquire a song template. Open-ended learners then experience a sensorimotor phase during which time they attempt to match their vocal production to that template, which ultimately results in a stable adult song. However, they are still able to continue to learn and modify their song throughout their lifetime. Canaries (*Serinus canaria*) are a good example of an open-ended learner. Canaries learn their songs during the spring, practice throughout the fall, then sing a crystallized song during the following spring (Nottebohm et al. 1986). This process is repeated every year, and thus their song repertoires expand and change annually.

Vocal mimics, a type of open-ended learner (e.g., parrots, *Psittacines*; lyrebirds, *Menura*; etc.), possess highly complex syrinxes which allow for these passerines to produce their species-typical vocalizations. In addition to learning vocalizations produced by other species, including human speech, vocal mimics can also imitate noises from their environment (e.g., chain-saw sounds, camera shutter). These complex vocalizations are integrated into their song resulting in a more complicated repertoire, which many individuals use to attract potential mates (Cocker et al. 2013).

Closed-ended learners only pass through the sensory and sensorimotor phase once, then their songs become relatively fixed for the rest of the birds' lives (Brainard and Doupe 2002). For zebra finches, the sensory and the sensorimotor phases overlap. These birds only produce one

song type, which is crystallized by 90 days post-hatch (Slater et al. 1988). Another developmental path is that of the white-crowned sparrows (*Zonotrichia leucophrys*) which learn their song in the first few months of life, but do not actually sing until the following breeding season (Marler 1970).

## Conclusions

Passerines are the largest order of birds, encompassing more than half of all known avian species. Oscines' ability to learn vocalizations from adults is rare and has only been observed in a limited number of species. This ability contributes to the size of song repertoires, and occasionally calls, observed within this group. Oscines' auditory systems, including their specialized ears and neural pathways, are consistent across songbird species. Oscine and suboscine species differ in the number of vocalizations in their repertoire (i.e., ranging from a few vocalizations to hundreds), the time during which vocalizations are acquired (i.e., during a single acquisition period, annually, or continually), and the underlying neural mechanisms used to produce these vocalizations. Overall, passerine communication is complex and critical for social dynamics, in particular for species that inhabit dense vegetation, communicate over long distances, and cannot rely on visual cues.

## Passive Avoidance Conditioning

### ► Passive Avoidance Learning

## Passive Avoidance Learning

Tina Peckmezian

Macquarie University, Sydney, NSW, Australia

## Synonyms

Fear learning; Inhibitory avoidance; Passive avoidance conditioning; Punishment

## Definition

Passive avoidance involves an organism learning to withhold a certain behavior in order to postpone or avoid an aversive event.

## Introduction

Learning to avoid harmful events, stimuli, or places has clear adaptive value and is ubiquitous across the animal kingdom. Experimentally, avoidance involves a subject learning that a specific behavioral response will result in the postponement or avoidance of an undesirable event.

Avoidance behavior is most commonly evaluated using either active or passive avoidance conditioning paradigms. In the active form, the aversive event is avoided by performing a specific response, while in the passive form the aversive event is avoided through the *suppression* of a specific response. The response to be performed or suppressed (the conditioned response [CR]) is typically one that the animal normally performs. In this case, the task is for the animal to learn to suppress a normal response when in a given context, and thus behave contrary to their innate preferences (Bammer 1982).

In both active and passive forms, learning the avoidance contingency results in the postponement or omission of a predictable aversive event (the unconditioned stimulus [US]). Avoidance procedures can be distinguished from escape procedures, in that the former involves behavior causing the omission of a *forthcoming* aversive event, while the latter involves distancing oneself from an *ongoing* aversive event (Bower and Hilgard 1981).

## Passive Avoidance Procedures

Passive avoidance conditioning utilizes one of two procedures: discrete trial or free-operant passive avoidance conditioning. In the discrete trial procedure, a distinctive warning stimulus occurs prior to the aversive event and conveys to the subject that the aversive event is forthcoming. To prevent or postpone the aversive event, the subject must withhold a specific response during the period that the warning stimulus is present (typically 5–60s in duration). In contrast, the free-operant or “punishment” procedure simply pairs a given spontaneous or learnt behavior to an aversive event, with the outcome that the specified behavior is suppressed.

A commonly used form of the free-operant procedure involves training a subject (typically a rat or mouse) in a two-chamber conditioning apparatus that contains both dark and light compartments. As many animals, including rodents, possess an innate tendency toward dark areas, a subject placed in the light compartment will

typically run to the dark compartment where it receives a single or continuous electric shock. The subject thereafter associates the dark compartment with the aversive event (Pavlovian contextual fear conditioning) and withholds entry into this previously punished area (instrumental response) during the subsequent test session. While electric shock is the most commonly used aversive stimulus in passive avoidance tests, puffs of air, loud noises, and extreme temperatures have all been used as well.

Since rodents acquire this task after a single trial, the passive avoidance paradigm is used extensively to study memory, in and of itself, as well as following physiological manipulations or drug delivery. Drug injections, for example, can be precisely timed before training or at different points after training and prior to the retention test, permitting the effects of a given intervention on encoding, consolidation, and retention to be clearly articulated. Likewise, the retention test can be conducted soon or long after training in order to separately assess short-term and long-term memories.

## Experimental Parameters

A wide range of experimental designs have been utilized to evaluate passive avoidance learning, and the procedural differences among these designs have led to significant variability in outcomes. One of the most critical parameters in avoidance paradigms is the intensity and duration of the aversive stimulus. Experiments with electric shock commonly demonstrate a stepwise improvement in avoidance behavior alongside increases in the intensity of the electric shock, up to a certain threshold, above which performance decrements or harm may be observed (Seligman and Campbell 1965). Also important is the relevance of the stimulus and desired response to the organism: stimuli and responses that are evolutionarily relevant to a species will be much more readily acquired than those that are arbitrary (Bolles 1970). For example, associations between taste and induced sickness are more readily acquired than associations between audio-visual

cues and sickness, and running is far more readily acquired by rats in response to an aversive stimulus than trained tail movements. Other factors, such as the temporal nature of stimulus exposure, the experimental context, handling by the experimenter, species-specific differences and differences between individuals may further impact the rate of acquisition and retention.

## Theories of Avoidance Learning

One of the earliest and most influential theories put forward to explain avoidance behavior is Mowrer's two-factor theory (Mowrer 1947), which suggests that avoidance learning is comprised of two processes: predicting a threat and learning to escape from the predictor. This theory asserts that avoidance behavior includes both a Pavlovian and instrumental component. The Pavlovian component occurs when a warning signal previously paired with an aversive stimulus elicits fear, while the instrumental component occurs when the aversive stimulus that was predicted by the warning stimulus is avoided. As a result, avoidance behavior is negatively reinforced through a reduction in fear.

While Mowrer's theory remains an influential explanation of avoidance processes, it has not escaped criticism. One critique concerns the finding that avoidance responses may occur in the absence of experimentally controlled warning stimuli. For example, in *unsignalled* avoidance procedures, animals are exposed to and learn to avoid an aversive stimulus that is delivered at fixed time intervals, and in the absence of a discrete warning signal (Sidman 1962). However, although explicit warning signals are absent in such cases, the "silent" temporal and proprioceptive information inherent within the experimental context may serve as a medium for association with the aversive outcome. Mowrer's theory may therefore still be viable, so long as the definition of what constitutes a warning stimulus is extended to encompass a broader range of contextual cues.

A second critique addresses avoidance behaviors observed in the absence of an initial aversive

experience. Since the two-factor theory assumes that avoidance is based on prior reinforcement learning, avoidance that occurs spontaneously and without exposure to an antecedent stimulus is in conflict with the two-factor theory. For example, avoidance to novel stimuli occurs frequently in naturalistic settings, where an initial encounter with harm can be fatal. In this context, even exposure to the scents of a never-before encountered predator can be sufficient to elicit an avoidance response or other defensive behaviors.

In response to these and other critiques, Seligman and Johnston (1973) put forth an alternative "cognitive" explanation of avoidance learning. Their theory argued that avoidance behavior is driven by expectancies about the response-outcome contingency, rather than stimulus-response associations. During avoidance learning, subjects acquire two response-outcome contingencies: (1) if they perform the appropriate avoidance response (including the omission of some behavior, as with passive avoidance), the aversive stimulus will not occur, and (2) if they do not perform the avoidance response, the aversive stimulus will occur. Subjects perform the avoidance response because they prefer to not experience the aversive stimulus. By including a role for expectancies in avoidance learning and maintenance, Seligman and Johnston's theory accounts for data not easily explained by two-factor theory. For example, many animals continue to perform an avoidance response long after the aversive stimulus has been inactivated. While the two-factor theory assumes that fear and fear-motivated avoidance behavior should gradually diminish once the aversive stimulus has been removed, Seligman and Johnston take an alternative view that deemphasizes the role of fear. According to cognitive theory, an animal that continues to avoid a stimulus that was previously associated with harm does not experience the changed contingency that occurred when the association between the stimulus and harm was removed. As such, the expectancy that harm will follow the previously harmful stimulus is preserved (Krypotos et al. 2015).

## Conclusion

The passive avoidance conditioning test is a well-described paradigm for evaluating the mechanisms involved in cognition. This test allows retention to be examined after a single training session and as such is routinely used in behavioral and neurophysiological research to examine the effects of novel chemical agents on learning and memory.

## Synonyms

[Father's behavior](#)

## Definition

Set of behavioral patterns exhibited by the male parent.

## Introduction

It is the set of characteristics and patterns associated with the father. The increased concern about the relationship between father and a child is attributable in explaining the belief that fathers can also have a significant influence on the development of their children. Paternal behavior is not common in mammals, but there are much evidences proving paternal behavior being regulated by the same neural circuits that controls maternal behavior. Since the mechanisms are very much similar in paternal and maternal behavior, it leads to an idea that parental circuit is common in mammals. Studies exhibit the vital role of paternal behavior and its influence on increasing the survivorship of offspring (Earls 1976). Testosterone is the most researched hormone which is believed to be affecting the paternal care. However, testosterone is prominently known for its negative effects, but there are facts which show that it can also encourage paternal

behavior in some species (Bredy et al. 2004; Lamb et al. 1985; Snowdon and Suomi 1982).

## Role of Biogenetic Factors in Paternal Behavior

According to many hormonal debates, it is proposed that mothers are more prepared in terms of hormones for the process of pregnancy, parturition, and lactation and other childcare tasks that are important for the survival and development of the offspring as compared to fathers. Therefore, it is believed that men do not have these capacities since they compulsorily need not to participate in childcare. However, there is no reason to consider that these behavioral susceptibilities are in any way deterministic, crediting female involvement in parenting and neglecting the involvement of male. Therefore, fathers can also perform the tasks of parenting as good as the mothers.

Clearly, a biogenetic perspective compels us to consider all the ecological factors explaining the environment in which the potential is displayed along with the physiological susceptibility (Lamb et al. 1985).

## Extent of Paternal Involvement

Psychologists and many researchers consider paternal behavior in a more illustrated way by considering a diverse array of activities where fathers are involved with their children. The amount of time spent by fathers in parenting activities like feeding, provisioning, conceiving, rearing, and protecting plays a very vital role in determining the paternal behavior in their children.

### Components of Paternal Involvement

Components of paternal involvement include various factors responsible for changing behavior in children. These components comprise of:

- Interaction of fathers with their children – It refers to the actual time spent by the fathers with their children through direct contact with

them by participating in caretaking and shared activities.

- Extent of fathers' responsibility toward their children – It refers to the role played by the fathers in ensuring the safety of the children and also making resources available for them.
- Availability of fathers for their children – It refers to the concept that in times of need, they must be potentially available for their children irrespective of the presence of direct or indirect contact (Earls 1976; Lamb et al. 1985).

## Paternal Behavior in Other Taxonomies

Involvement of males in the care of offspring is common in many other species other than mammals. Only 5–10% of mammals exhibit paternal care, of them rodents, primates, and canids are few. In teleost fish species, males play a more vital role than females in nest building and egg attendance.

In birds, around 90% of the species share responsibilities among both the parents including nest building, incubation of eggs, and defending and feeding to the offspring. In bird population, which of the parent will care for the offspring is determined by the available sex ratio. For example, male shorebirds which are more abundant in population as compared to female shorebirds are more likely to take care of the offspring (Cockburn 2006).

A large number of species of anuran amphibians also exhibit paternal behavior like glass frogs. Some species of arthropods also show paternal care like giant water bug, harvestman, etc. Fathers, in many species of crustaceans, play a vital role in building nests or burrows. The most uncommon aspect of paternal care in arthropods includes the investment of males after egg giving, and it exists in only 13 taxa (Brown et al. 2010; Dulac et al. 2014; Smith 1997; Tallamy 2001; Woodroffe and Vincent 1994).

## Sensory Cues in Paternal Interactions

Many researchers and neuroethologists are working to recognize and estimate the stimulating

differences in the nature and complexity of the signals which are responsible for driving paternal behaviors. According to recent studies, it is believed that the vomeronasal organ (VNO) plays a somewhat vital role in determining the infanticidal and paternal behavior. In laboratory mice, infanticide is more common in virgin males.

Recent research in mice also states that the loss of VNO either by surgical or genetic means leads to the significant decrease in the pup-directed aggression and stimulates parental care in virgin males. Virgin rats at first find foreign pups aversive, but their continuous exposure to pups stimulates paternal care. Exposure to pups leads to the stronger activation of the neurons in the vomeronasal pathway in the virgin males as compared to the fathers, and the impairment in the VMO due to its removal leads to decrease in pup-directed aggression and stimulation of paternal care.

In laboratory mice, it is also observed that males after mating with a female stop committing infanticide from the time of birth to the weaning of pups due to the stimulation of the adaptive mechanism that prevents a male mouse from killing its own pups due to the olfactory cues released by the pups (Dulac et al. 2014; Horrell et al. 2018; Marler et al. 2003; Numan 2014).

### Paternal Interactions Underlying Neural Circuits

Neural circuits which are responsible for underlying paternal behaviors come from genetic studies done on mice. Virgin male rats avoid physical contact with foreign pups and then eventually exhibit paternal care after the process of sensitization. Moreover, recent genetic studies have shown that male interaction with the offspring is also influenced by the changes taking place in the hormonal levels. In many species of vertebrates where males participate in paternal care, the levels of testosterone decrease during the fatherhood such as in humans, frogs, etc. (Numan 2014).

Experiments that involve mapping of the brain areas have demonstrated several brain

areas which are responsible for controlling parental behavior like adjacent ventral bed nucleus of stria terminalis (vBNST) and medial preoptic area (MPOA). Lateral septum is also found to be essential in control and regulation of the parental behavior. The electrical stimulation of preoptic area also induces paternal care in males. Further, optogenetic activation of the neurons in the area stimulates pup grooming and paternal care in virgin males.

The regions of brain which are responsible for regulation of the paternal care are highly heterogeneous structures. Many of the newly designed genetic and molecular tools make it easy to identify precise subsets of neurons which allow a deeper understanding of the associated neural behavior circuits (Dulac et al. 2014; Numan 2014).

### Role of Hormones in Paternal Behavior

Prolactin is an important peptide hormone and has many important functions like lactation regulation and sexual gratification and is also involved in proliferation of oligodendrocyte precursor cells. Prolactin is also believed to play a very important role in the onset and maintenance of paternal care in variety of species. According to many studies, the concentration of prolactin increases in fathers during the first weeks after the birth of their first child. High levels of prolactin help fathers to be more alert and respond more positively toward their children (Hashemian et al. 2016).

Cortisol is a stress hormone in humans. Cortisol has a significant role in paternal involvement as it determines the various behaviors like the bonding between the father and the child, experience of paternity, social affiliations, etc. However, the levels of salivary cortisol increases in the expectant fathers in the last week before delivery probably due to the increased anxiety levels in fathers regarding the birth of the offspring. The levels of cortisol

decrease after the delivery and are also found lower in non-fathers.

Testosterone is the principal male sex hormone. Similar to cortisol, testosterone levels also increase before the birth and then gradually decrease after the child is born. It is also observed during many studies that the presence of baby cues can stimulate the production of testosterone in the saliva of fathers. Many studies also show that males tend to have higher levels of vasopressin as compared to females. Vasopressin levels in fathers help in bonding formation and also extend social behavior. The paternal hormonal responses in humans are believed to be dependent on environmental and social stimuli. These variations support paternal behavior and could increase or decrease the quantity and quality of care for the children by the fathers (Marler et al. 2003; Nunes-Costa et al. 2014; Wynne-Edwards and Timonin 2007).

### **Influence of Paternal Behavior on Offspring**

Paternal behaviors can lead to variety of influences on the children. Impacts of paternal involvement on children usually comprise of, in terms of survival, health, cognition, emotional capacity, socioeconomic development, language development, reproductive parameters, etc. The influence of paternal behavior on children can begin before birth. The physiological impacts can be inherited by fathers through genetic and epigenetic mechanisms. These impacts can also influence the maternal investment during the pregnancy (Wynne-Edwards and Timonin 2007).

According to many experimental studies, older fathers tend to transmit more mutations to their children. A variety of research on paternal behavior also suggests that fathers play a very important role in the development of cognition in their children. Paternal involvement tends to reduce negative social behavior in boys and psychological-related problems in girls during the phase of early adulthood (Earls 1976; Lamb et al. 1985).

### **Paternal Inheritance in Cognition**

X chromosome gene inheritance plays a very vital role in the development of intelligence and related cognitive skills. This is due to the fact that X chromosome contains a large number of genes responsible for intelligence and cognition. The male offspring receives the one and only X chromosome from their mothers, but this is not the case for female offsprings who receive their X chromosomes from both the parents. But the X chromosome which daughters receive from their fathers is exactly the same which they have got from his mother (daughter's paternal grandmother). So, the X chromosome inherited by the daughter from her mother is a mix of genes from both of her mother's Xs. Thus, the daughter's maternal X chromosome does not match completely to her mother's X, whereas her paternal X chromosome matches completely to her father's X. Therefore, this makes the relatedness of the daughters to their fathers more similar as compared to the relatedness to their mothers.

This also explains the fact that cognition and intelligence associated with paternal behavior has more influence on the daughters as compared to the sons. So, if the paternal X chromosome is expressed more disproportionately in the brain, then the daughters might be more similar to their fathers in terms of cognition instead of their mothers (Badcock 2011).

### **Conclusion**

Various studies on relationship between a father and child provide a lot of information about the role of fathers in the development of their offspring and the extent of paternal behavior. Many researches explained that the fathers also play a very significant role in parenthood and this is not only true for humans but also observed in many other species (Gubernick and Teferi 2000). In this chapter, various aspects of paternal behavior have been underlined like

the role of biogenetics, sensory cues involved, influence of various hormones, paternal interactions underlying neural circuits, etc. (Snowdon and Suomi 1982).

A large number of studies indicate various molecular mechanisms that are able to regulate paternal behavior in humans. Remarkably, neural circuits that regulate parental interactions with offspring are present in both the male and female brains (Dulac et al. 2014; Lamb et al. 1985; Nunes-Costa et al. 2014). Therefore, more future studies on paternal behavior will unravel the complexity of its interactions and will provide us a better understanding.

## Paternity Certainty

Rachel Schepke and Todd K. Shackelford  
Department of Psychology, Oakland University,  
Rochester, MI, USA

### Synonyms

Cuckold; Cuckolded

### Definitions

Paternity certainty refers to the degree to which a male is certain that his partner's offspring is genetically his own. Alternatively, paternity uncertainty is the degree to which a male is uncertain that his partner's offspring is genetically his own. Cuckoldry occurs when a male invests in offspring that are not genetically his own.

### Introduction

Paternity certainty is a concern primarily for males of species in which females gestate offspring. Whereas females are certain of maternity, males risk the costs of cuckoldry – investing in offspring to whom they are not genetically related. Males are more likely to invest in a partner and offspring when paternity certainty is higher (Propkop et al. 2010). Contrarily, males are more likely to abandon a partner and offspring or to invest less in them when paternity uncertainty is higher (Buss and Abrams 2017; Graham-Kevan and Archer 2011; Pagel 1997). A male's paternity certainty thus has implications for his reproductive success.

### Factors that Influence Paternity Certainty

Paternity certainty is influenced by a female partner's behavior. Females that display sexual faithfulness to their partner thereby increase his

paternity certainty. By abstaining from extrapair copulations, the female is less likely to be inseminated by another male. Females may display sexual exclusivity toward their partner by ignoring other males, living with their partner, and copulating frequently with their partner, especially during times of greater female fertility (Ludwig and Becker 2006; Shackelford et al. 2015). Females experience greater fertility during ovulation or estrus. Although ovulation and estrus are often not accurately detected by either sex, females of some species, including birds, lions, and primates, display greater sexual interest, sperm retention, and conception rates during higher fertility times (Baker and Bellis 2014/1995). Males may display mate guarding behaviors to increase their paternity certainty. Mate guarding behaviors include keeping the female away from other males, discouraging the female from abandoning him, and frequent copulation with the female (Baker and Bellis 2014/1995; Buss and Abrams 2017; Shackelford et al. 2015).

Internal female fertilization can threaten paternity certainty and increase a male partner's risk of cuckoldry. During copulation, the male's sperm travel directly into the female's reproductive tract toward the egg. However, other male's sperm may be in the female's reproductive tract, posing a threat to the current male's paternity. Sperm competition refers to two or more males' sperm competing to fertilize a female's egg. Sperm competition is higher in polygamous species and when two or more males have sexual access to the same female within a sufficiently brief period of time (Baker and Bellis 2014/1995; Shackelford et al. 2015).

Sperm displacement, sperm quality, and copulatory plugs can increase paternity certainty via sperm competition. In some species, such as humans and crabs, the penis acts as a sperm scooping device to remove a previous male's sperm before depositing the male's own sperm – a phenomena known as sperm displacement (Baker and Bellis 2014/1995; Shackelford et al. 2015). In some species, such as bush babies, king cobras, beetles, and moths, the penis can inflict wounds in the female during copulation, allowing sperm to flow directly into the female's

bloodstream, increasing the chance of fertilization (Schilthuizen 2014). Across species, the quality of sperm is higher when sperm competition is more intense. In humans, the first few drops of ejaculate contain more sperm and swim toward the female's reproductive tract with more power, thus increasing the chance of fertilization (Baker and Bellis 2014/1995). These sperm may have a better chance of fertilizing the egg compared to sperm already present in the reproductive tract. Furthermore, females typically retain more sperm for fertilization when the sperm quality is higher and/or the male is more desirable. Males of some species, including snakes, mammals, and insects, produce copulatory plugs after ejaculation which may prevent their sperm from being ejected by the female or block a subsequent male's sperm from reaching the egg (Baker and Bellis 2014/1995; Barker 1994). After conception occurs, the physical appearance, odor, or other cues to genetic relatedness of offspring may provide a last line of defense against cuckoldry in some species such as social insects, fish, birds, and mammals (Dolinska 2019; Pagel 1997). In humans, for example, physical resemblance between the sire and offspring may signal genetic relatedness, providing assurance of paternity.

It is not uncommon for females to change mates, especially in polyandrous species and between breeding seasons. Nonetheless, females that engage in extrapair copulations increase a male's paternity uncertainty. Females may attempt to hide evidence of sexual unfaithfulness to avoid being abandoned due to threatening the male's paternity. However, whether the female was sexually unfaithful, a male's paternity certainty assessment decreases when he perceives sexual infidelity occurred. Strange scents, changes in sexual interactions, unexplained absences, and promiscuity on behalf of the female increase the male's paternity uncertainty (Baker and Bellis 2014/1995; Graham-Kevan and Archer 2011). Females may acquire scents from other males with whom they copulated. Females that engage in extrapair copulations may alter sexual interactions with a primary partner, including

copulating less frequently or for a shorter duration. Unexplained absences may indicate the female left their habitat to copulate with other males. Females that flaunt their attractiveness may be attempting to attract other males.

## Implications for Paternity Certainty

In many species with paternal investment, males that are more certain of paternity invest more in their putative offspring and partner. Males that invest time and resources into genetically related offspring thereby increase their reproductive success. In many species (e.g., humans; Hill and Hurtado 1996), offspring reared by both parents may be more likely to survive and produce offspring. Conversely, in some species such as humans, insects, birds, and mammals, increased paternity uncertainty is associated with greater male sexual coercion, mate guarding, physical abuse, abandonment, and infanticide (Baker and Bellis 2014/1995; Graham-Kevan and Archer 2011; Shackelford et al. 2015). When paternity uncertainty is high, males may force the female to copulate to increase the chance of conception. Males may also keep their female partner in close proximity more frequently to prevent her from copulating with other males. Females are at greater risk for being physically abused by their partner when paternity uncertainty is higher.

## Conclusion

Paternity certainty influences sexual interactions, sperm competition, allocation of resources, and investment in a partner and putative offspring. The degree to which paternity certainty fluctuates depends on the female's sexual behaviors and, in some species, the physical appearance of offspring. Positive outcomes, such as increased paternal investment, are associated with increased paternity certainty, and negative outcomes, such as abandonment, are associated with increased paternity uncertainty.

## Pathogen

Jacqueline Hill Tudor  
Ohio University, Lancaster, OH, USA

## Synonyms

[Disease-causing agent](#); [Infectious agent](#); [Infectious particle](#)

## Definition

Pathogenic microbes, or *pathogens*, have an ability to produce harm in a host organism and exhibit a parasitic or predatory relationship with the host. Pathogens cause infectious diseases such as streptococcal pharyngitis, influenza, botulism, rabies, gastroenteritis, and Creutzfeldt-Jakob disease.

## Introduction

Microorganisms, or microbes, are unicellular or multicellular organisms too small to be seen with the unaided eye (Cowan 2018). Microbes are ubiquitous in the internal and external environments of humans and animals; thus, humans and animals often act as host organisms for microbes. While many microbes in a host's microbiome are harmless or beneficial to the host, the relationship

between a microbe and a host can be a complicated one. Animal hosts can exhibit mutualistic, commensal, cooperative, parasitic, or predatory relationships with microbes. An animal host and microbe that exhibit reciprocal benefits and dependency upon each other share a mutualistic relationship. In the event that a host or microbe benefit from the relationship while the other is unharmed, they are said to share a commensal relationship. Cooperative relationships are beneficial to both the host and microbe, but the relationship is not required for survival. Parasitic and predatory relationships are those in which either the host or microbe will benefit at the expense of the other. The difference between parasitic and predatory relationships is difficult to define. However, parasitic relationships require a coexistence of host and microbe for at least some period of time, while predatory relationships do not (Willey et al. 2017). Parasitic or predatory microorganisms that produce direct or indirect harm to a host are said to be pathogens.

## Classification of Pathogens

Pathogens may be cellular or acellular entities. Cellular pathogens exist across all three domains of life, including *Bacteria*, *Archaea*, and *Eukarya*. However, most cellular pathogenic organisms belong to the domain *Bacteria*. Acellular pathogens include both viruses and prions (infectious proteins). All pathogens are capable of producing harm, disease, or infection in the host. The term *pathogenicity* refers to the ability of a microbe to produce illness in a host, while *virulence* of a pathogen refers to the degree of pathogenicity. Many pathogens are classified by the severity and type of damage it can inflict upon a host, with host-specific considerations such as health of host, taken into account. For instance, some pathogens are able to produce disease in a healthy host and are termed *true (primary) pathogens*. Other pathogens are able to cause disease only in immunocompromised hosts and are termed *opportunistic pathogens* (Talaro and Chess 2012). Pathogens may also be classified by their location within the host. *Extracellular pathogens* remain in the

extracellular fluid surrounding the host cells but do not enter the cells. *Intracellular pathogens* grow and divide inside host cells (Willey et al. 2017). There are also practical classifications for pathogens. The biosafety levels (BLS) are aimed at promoting worker safety when handling infectious microorganisms; the BLS of an infectious agent takes into account virulence and transmission route in safe-handling protocols (Biosafety in Microbiological and Biomedical Laboratories 2019).

## Pathogen-Host Interactions

The cells, tissues, organs, and fluids of animals represent ideal growth conditions for animal pathogens. Yet, the interior of the animal body is generally sterile. This is achieved by use of biological defenses, such as innate and adaptive immune defenses. Innate defenses are composed of anatomical barriers (i.e., skin and mucous membranes), sensor systems recognizing molecular patterns of pathogens or tissue damage, immune surveillance, phagocytosis, and inflammation. Adaptive immunity is a defense mechanism utilized by vertebrates to allow for more sophisticated protection from infection. For instance, adaptive immunity relies on the ability of the immune system to recognize a specific pathogen, mount an immune response to destroy the pathogen, and remember the pathogen. Such a process confers the host *immunity*, or resistance to infection or disease caused by that pathogen. All types of body defenses rely upon distinguishing between self (host) and nonself (pathogen). Antigens are membrane-localized glycoproteins or glycolipids (Nester 2012) utilized by organisms for recognition of self vs. nonself. Additionally, pathogen-associated molecular patterns (PAMPs), such as cell wall components, flagellin molecules, and viral RNA, are expressed by pathogens and can trigger host defenses (Nester 2012). Host immune cells express pattern recognition receptors (PRRs) that bind or detect PAMPs, thereby aiding in the host's detection of a pathogen.

## Characteristics and Strategies of Pathogens

If a pathogen penetrates the first line of defense (i.e., skin or mucous membranes) and gains entry into an animal, the pathogen must rapidly adapt to the host environment. Pathogens express *virulence factors* capable of facilitating infection by evading or outcompeting host defenses. Segments of pathogen DNA coding for virulence factors are called *pathogenicity islands*; *pathogenicity islands* may be transferred between members of a microbial species in a process called horizontal gene transfer (Schmidt and Hensel 2004). Virulence factors can be *adherence factors* that permit physical attachment of the organism to host, *invasion factors* that facilitate spread to other cells, or *toxins* that negatively alter the metabolism of the host cell (Willey et al. 2017). Not all members of a microbial species produce the same virulence factors. In fact, some members of a microbial species may not produce any virulence factors. For instance, most strains of *Escherichia coli* (*E. coli*) are nonpathogenic and relatively harmless to animal hosts. Nonpathogenic *E. coli* are helpful members of the mammalian intestinal microbiota, where they are known to aid in nutrient metabolism. Pathogenic strains of *E. coli* are responsible for bouts of gastroenteritis (inflammation of stomach and intestines) associated with contaminated food sources; pathogenic *E. coli* express virulence factors that nonpathogenic *E. coli* do not. There are six known pathotypes of *E. coli* with each pathotype of *E. coli* expressing different virulence factors. For example, the enterotoxigenic *E. coli* (ETEC) pathotype produces virulence factors called enterotoxins. Heat-stable enterotoxin (ST) and heat-labile enterotoxin (LT) act to increase electrolyte and water content of the intestines, thereby producing symptoms of ETEC gastroenteritis, such as watery diarrhea. The ETEC *E. coli* pathotype is known to cause traveler's diarrhea and is found in contaminated water, as well as raw fruits and vegetables. Conversely, enterohemorrhagic *E. coli* (EHEC) expresses a different toxin, Shiga toxin, which kills vascular endothelial cells and produces severe, bloody diarrhea.

EHEC is found in raw or undercooked ground beef and unpasteurized fruit juices (Croxen et al. 2013). The virulence factors that allow pathogens to penetrate, grow, and thrive cause infection or disease in the host.

## Establishing Infection: Invasion, Adhesion, and Colonization

Pathogens produce a variety of invasion factors which allow for microbial penetration into the host. The microbial penetration process may be active or passive. Active penetration occurs when a pathogen produces and releases lytic substances that alter the host tissue by destroying the host's extracellular matrix or basement membrane underlying epithelial tissue, destroying glycocalyx components, or triggering a rearrangement of the host cell membrane. For example, *Clostridium perfringens* (causative agent in clostridial gas gangrene) produce an invasion factor called collagenase which destroys collagen molecules found in connective tissues (Petit et al. 1999). Destruction of connective tissue by collagenase allows for *C. perfringens* to penetrate and spread into the deep tissues of the body. The invasiveness of pathogens varies, however. Some pathogens utilize passive penetration mechanisms. Passive penetration occurs when the first line of defense is damaged and a pathogen enters the host through a lesion, wound, abrasion, damaged mucous membrane, or otherwise damaged/inflamed tissue (Willey et al. 2017). In passive penetration, the pathogen takes advantage of the weakened host first line of defense.

After a pathogen has gained entry into the host organism, it must adhere to the target cell and colonize. Adherence usually requires the pathogen to have specialized structures, such as *fimbriae* or *pili*, to attach to the host cell. Fimbriae and pili are examples of bacterial adherence virulence factors. Yet, pathogens can express a wide variety of attachment structures; all are well-suited to attach to a designated host cell. For example, influenza virus utilizes a hemagglutinin (HA) spike protein for viral adherence to  $\alpha$ -sialic acid on the membranes of host upper respiratory tract cells (Luo 2012).

After adhesion is complete, the pathogen will colonize (actively reproduce). Pathogens also possess ways to elude the immune system once established, whether it be by hiding inside a host cell (*Shigella*), attacking immune cells (*Streptococcus pyogenes*), or surviving phagocytosis (*Salmonella*) (Willey et al. 2017).

## Damage to Host

Many pathogens enter, adhere, and colonize within a host organism, thereby taking valuable nutrients and resources from the host organism. Yet, there are other ways in which pathogens can inflict damage on a host organism, including the release of toxins. Toxins are substances encoded for by the genetic material of bacteria, fungi, and viruses which change the normal metabolism or activities of a host cell in such a way as to benefit the pathogen while harming the host. The two major classes of toxins are exotoxins and endotoxins. Exotoxins are heat-labile proteins that are released from the microorganism into the surrounding environment; they are inactivated at 60–80 °C. The food-borne disease botulism is caused by products of the bacterium *Clostridium botulinum*; *C. botulinum* produces the exotoxin *botulin* which blocks acetylcholine release at the neuromuscular junction. The botulin toxin prevents neuromuscular communication and produces flaccid muscle paralysis. In the case of food-borne botulism, the individual ingests food contaminated with the heat-stable toxin. Botulism can occur when low-acidity foods are improperly canned (Nester 2012). Ingestion of the botulin toxin causes the symptoms associated with botulism, not the bacterium itself (except in cases of infant botulism). The *E.coli* enterotoxins (Shiga toxin, ST, LT) discussed in the previous section are also examples of exotoxins. Endotoxins, such as lipopolysaccharide (LPS), are found within the cell walls of Gram-negative bacteria. When the animal immune system destroys the Gram-negative bacterial cell, the endotoxin is released into the blood and produces widespread deleterious effects, such as fever, hypotension, organ

failure, and blood coagulation. The net result of LPS activity is often referred to as septic shock (Willey et al.). Fungi are also capable of producing toxins called mycotoxins. *Aspergillus flavus* produces aflatoxins; aflatoxins are known to cause liver disease and liver cancer (Cowan et al.). Viruses are nonliving pathogens capable of utilizing host cell machinery to produce dangerous toxins. Rotaviruses are common causative agents in viral gastroenteritis. Rotaviruses encode an enterotoxin called NSP4 that induces vomiting in a serotonin-dependent mechanism (Hagbom et al. 2011). Thus, the ability of pathogens to produce signs and symptoms associated with infectious disease reaches beyond its ability to invade the body's tissues. Over generations of microevolution, pathogens continue to evolve to become more effective pathogens, whether by finding new ways to elude the host immune system or produce more effective virulence factors.

## Patrick Bateson

Kevin N. Laland

University of St Andrews, St Andrews, UK

Paul Patrick Gordon Bateson (known as “Pat”) was born on March 31, 1938. Bateson decided from an early age that he would be a biologist, influenced by the legacy of the famous cousin of his grandfather, the geneticist William Bateson. Patrick Bateson was educated at Westminster School before beginning an undergraduate degree in Natural Sciences at Kings College Cambridge University in 1957. In 1963, he married Dusha Matthews and had two daughters, Melissa born 1968 and Anna born 1972. With the exception of a 2-year Harkness postdoctoral fellowship spent working with neuroscientist Karl Pribram at Stanford University, Bateson spent the remainder of his career based in the Zoology department at Cambridge, where he is currently Emeritus Professor of Ethology. His early career was greatly influenced by Niko Tinbergen and Robert Hinde, the latter supervising his PhD on the topic of behavioral imprinting, in the Sub-Department of Animal Behaviour.

Patrick Bateson has made outstanding contributions to the study of animal behavior over a 50-year period, and is now regarded as a world leader in this field, with particular expertise on behavioral development. While Bateson’s research has included investigation of virtually every topic in animal behavior, he is perhaps best known for his research on filial imprinting, involving analyses of the causal mechanisms, development, function, and evolution of this behavioral trait, including work in the laboratory and field. This work, encompassing much experimentation and theory, has included highly intricate and innovative behavioral neuroscience, in collaboration with Prof. Gabriel Horn, which has pioneered new methods, set new standards for behavioral research, shed new light on the interplay of internal and external factors during behavioral development, and become a textbook classic, not just in behavior but adjacent fields. Bateson investigated what ended the sensitive period for imprinting, concluding that it was due to a process of competitive exclusion. Experience with one class of objects made it more difficult for the birds to form attachments to another class and the greater the stimulus value of the first class the more quickly would be the exclusion effect. He later found that once birds had been imprinted, they could use this perceptual experience to help them in discovering new sources of food. This research led to the recognition that imprinting shared many features with perceptual learning and that Konrad Lorenz’s earlier claim that this was a special form of learning was wrong.

Bateson has also made outstanding contributions to the study of mate choice, animal welfare, play, creativity, learning and memory, and the active role of behavior in evolution. He has been a leader in the field of ethology, developing more nuanced understandings of many difficult issues, such as “instinct” and “learning,” and has taught many of us how to think about these topics in the process. He has also shown courage, integrity, sensitivity, and leadership in tackling thorny and emotive issues, such as deer hunting and nonhuman primate research, and standing up against overly simplistic adaptationism and gene-centric accounts.

Bateson has published over 300 scientific articles in leading journals, as well as several influential books, many of which have run to multiple editions. His book *Measuring Behaviour*, with Paul Martin, now in its third edition, has been universally regarded as the definitive methodological introduction for students of animal behavior for decades, and helped turn the field into a rigorous quantitative science. Another book *The Domestic Cat*, with D.C. Turner, is a huge best seller, also in its third edition. Other edited volumes, notably *Growing Points in Ethology* in 1976, and *Mate Choice* in 1983, had massive impact and shaped thinking in these fields. Bateson also edited the influential *Perspectives in Ethology* series for 20 years and was editor of *Animal Behaviour* for 5 years.

Patrick Bateson's contribution to science has been recognized with many honors, notably his election to Fellowship of the Royal Society in 1983. He was knighted in 2003 in recognition of exceptional contributions to behavioral research and British science more generally. He was director of the Sub-Department of Animal Behaviour at Cambridge for 10 years and was also Provost of Kings College, Cambridge, President of the Zoological Society of London, and both Biological Secretary and Vice-President of the Royal Society for many years. He has chaired numerous national committees, in the process bringing a balanced judgment to many difficult issues related to animal behavior, including the use of animals in medical research, dog breeding, and hunting.

In spite of his success and recognition, Patrick Bateson remains an approachable and affectionate scientist and colleague. He is famously dedicated to his students, lab members, and collaborators and always made time for anyone who would like to discuss their research. His commitment to undergraduate teaching is legendary, and he continued to teach for many years postretirement. Students greatly valued the personal touch that he brought to their education – he typically knew them by name and took great interest in their development. He is an exceptional mentor to numerous graduate students, postdocs, and junior collaborators, many of whom have gone on to have very successful careers in animal behavior.

---

## Pattern Learning

Shannon Kundery  
Department of Psychology and Counseling, Hood  
College, Frederick, MD, USA

### Synonyms

[Rule learning](#); [Sequence learning](#); [Sequential pattern learning](#); [Serial pattern learning](#)

### Definition

A cognitive operation whereby organisms detect and process repetitive (often rule-based) information from the environment. This subsequently allows the organism to respond more efficiently when the stimuli are next encountered.

### Introduction

Patterned sequences, series of events happening repeatedly and in a predictable way, are ubiquitous. For example, the seasons occur in the same order each year. Detecting and learning about the relationships among events happening recurrently in predictable ways facilitate organisms' survival

by allowing them to respond in a more efficient and appropriate manner. For instance, knowing that spring comes after winter enables humans with limited wardrobe space to cull warmer clothing in favor of cooler clothing during that seasonal transition each year. Thus, recognizing and learning about patterned sequences enable organisms to make predictions about upcoming events and react appropriately.

While some repeatedly occurring events that organisms respond to are organized in a meaningful way, others are not. Whether such organization within the sequence is present impacts how organisms learn about these sequences or patterns as well as their ultimate responses to these events. Researchers continue to investigate organisms' abilities to learn patterns of information and the processes underlying those abilities by studying humans and nonhuman animals across taxa (for review, see Fountain et al. 2012).

### Sequence Organization

Early on, researchers noted that sequences organized in a meaningful way that could be described using a “rule” were learned more quickly and with fewer errors than sequences without such organization. Additionally, such organization led organisms to be able to extend the sequences successfully. For example, Fountain and Hulse (1981) found that rats learned to run more slowly in a runway for decreasing quantities of food pellets when a general “less than” rule (14-7-3-1, where digits represent quantities of food pellets) was present for each successive run within a block of trials compared to a group for which the rule was absent (14-3-7-1). Additionally, when the rule was present, rats were able to better predict a new 0-pellet element added to the end of each sequence.

Meaningful organization likely improves learning, memory, and performance by reducing memory load. When meaningful organization is present, organisms can record or “chunk” the information from the sequence into smaller sets or groups of information, which increases the efficiency of and capacity for learning new

information (e.g., Terrace 1987). Chunks usually are made up of familiar or otherwise significant bits of information that are then recalled together later on. For example, the string WHOFBUIUSA would likely be remembered better than the string WOBUAHFIS, even though the letters in each are the same, because the first string contains three three-letter acronyms familiar to many. This familiarity enables chunking of the information for easier and more accurate later recall.

Additional studies have confirmed the importance of organization to pattern learning and performance by investigating the impact of inconsistencies in the rule or rules governing the sequence's structure. Many of these studies have been conducted with rats or mice using a variation of a Skinner box with eight walls (octagonal chamber) or a computer analogue of this task for humans. This has allowed for exploration of learning longer and more complex patterns across species. In the rodent version of the task, rats learn to make responses on the appropriate wall of the chamber (designated 1–8 clockwise) using a nosepoke or lever in the proper order for reinforcement. Humans complete an analogous two-dimensional version of this task using a computer. In this task, they are presented with eight circles on the screen arranged in a circular fashion (designated 1–8 clockwise) and must learn to make responses to the appropriate circle using either a touchscreen or a mouse.

For example, Fountain and Rowan (1995) investigated the impact of violations of pattern structure on humans' and rats' performance. Humans and rats learned either a pattern with no inconsistencies in pattern structure (123-234-345-456-567-678-781-812...) or a pattern with two inconsistencies in pattern structure (123-234-543-456-567-876-781-812...). Both humans and rats took longer to learn the pattern with inconsistencies and made more errors while learning, reinforcing the notion that meaningful sequence organization facilitates learning and performance and that violations of sequence organization impair learning and performance.

Many recent studies suggest that a variety of species possess the ability to at least minimally abstract rules and chunk information in serial

pattern learning tasks. However, the conditions under which they might do so may vary across species. For example, Garlick et al. (2017) explored pigeons' abilities to learn sequential patterns. While pigeons abstracted the structure of the sequence, they only did so when low-level feature-based information was reduced.

## Pattern Complexity

Sequences of information vary in their level of meaningful organization as well as their complexity. Complexity refers to the number of rules required to represent a pattern. Some patterns can be described using one rule (e.g., 1111111, repeat 1), while others require many rules for complete description. For example, the "runs" pattern 123-234-345-456-567-678-781-812 in the octagonal chamber task described previously requires five rules for representation: (1) start by choosing the receptacle on wall 1, (2) move over one wall in the clockwise direction to choose the next receptacle, (3) repeat rule 2, (4) move over one wall in the counterclockwise direction to choose the next receptacle, and (5) repeat rules 2–5.

A variety of research indicates that patterns that can be described accurately using a fewer number of rules are easier to learn than those requiring greater numbers of rules for complete description (e.g., Fountain and Rowan 1995). For example, Fountain and Rowan (1995) also explored humans' and rats' learning of patterns whose length was constant but whose complexity varied. Humans and rats learned a pattern that could be described using a fewer number of rules (123-234-345-456-567-678-765-654-543-432-321-218) or one that could be described using a greater number of rules (123-234-345-432-321-218-765-654-543-456-567-678). Neither pattern contained any violations of pattern organization. Results indicated that the pattern that required more rules for accurate description took longer to learn and more errors were committed by both rats and humans during learning, suggesting that greater pattern complexity was related to greater learning difficulty.

Pattern complexity is also heightened when two subpatterns (ABCDE, MNOP) are interleaved (AMBNCODPE). This is because organisms must initially recognize the relationships among elements that are not next to one another within the interleaved subpattern before abstracting the subpatterns' individual structures. The relationships among elements within each subpattern must be abstracted over one or more intervening elements from the other subpattern, heightening pattern complexity. That is, a human would need to recognize that A, B, C, D, and E belong to one subpattern and M, N, O, and P belong to another subpattern as well as that for each successive serial position in each subpattern one needs to advance one serial position in the alphabet. A human could then use this information to determine the next likely element in the pattern, in this case "Q."

Studies of organisms' abilities to learn interleaved patterns suggest that they are not just linking one item with the next using pairwise associations. Instead, they appear to be representing the abstract rules describing the subpattern sequences and their relationship to the overall interleaved pattern (Fountain et al. 2012). For example, in Fountain et al. (1999), rats learned either a structured (123-234-345-456-567) or unstructured (153-236-345-426-547) subpattern interleaved with repeating responses on lever 8 (structured 182838-283848-384858-485868-586878; unstructured 185838-283868-384858-482868-584878) in the octagonal chamber task described previously. Results indicated that the rats learned the interleaved pattern with the structured subpattern more quickly and with fewer errors than the interleaved pattern with the unstructured subpattern. The rats showed sensitivity to the relationships between the elements of the structured subpattern even though they were not located next to one another in the interleaved pattern.

The clarity of the relationships among the elements of the subpatterns can also affect pattern learning. The presence of irrelevant relationships among pattern elements can affect the induction of the rules describing a sequence. These relationships can distract from the correct induction of the

rules describing the pattern. For example, in Kundey and Fountain (2011), rats learned a runs subpattern (123-234-345-456-567) interleaved with repeating responses on lever 2 (122232-223242-324252-425262-526272), lever 6 (162636-263646-364656-465666-566676), or lever 8 (182838-283848-384858-485868-586878) in the octagonal chamber task described previously. Interleaving the same runs subpattern with repeating responses on lever 2, 6, or 8 produced differing amounts of potentially confusing irrelevant relationships in the overall interleaved pattern as well as varied the placement of these irrelevant relationships. Interleaving the runs subpattern with repeating responses on lever 8 produced no irrelevant relationships. Interleaving the runs subpattern with repeating responses on lever 2 produced irrelevant relationships at the beginning of the interleaved subpattern, while interleaving the runs subpattern with repeating responses on lever 6 produced irrelevant relationships at the end of the interleaved subpattern. The results indicated that the presence of any irrelevant relationships negatively impacted learning and that irrelevant relationships at the beginning of the interleaved pattern were more detrimental to learning than those at the end of the pattern. These results also support the general relationship between heightened pattern complexity and learning difficulty. Moreover, they hint that rats, like humans, process sequences of information from beginning to end in their search for potential structure within a sequence.

## Conclusion

Beyond understanding the basic cognitive phenomena underlying the ability to learn patterns of information, sequence learning tasks have broad applications to other areas of research. These include sex differences (Kundey et al. 2019), attention concerns (Kundey et al. 2011), and diseases involving motor learning (e.g., Willingham 1998).

For example, Kundey et al. (2019) found that male mice learned serial patterns more quickly as pattern complexity increased. While males and females learned single alternation (right-left-

right-left. . .) and double alternation (right-right-left-left. . .) patterns at similar rates, males learned a runs (123-234-345-456-567-678-781-812) pattern more quickly than females did.

Pattern learning tasks can also be helpful in illuminating the impacts of differences in ability to attend and ways to reduce these impacts. For instance, Kunder et al. (2011) found that college students' learning of serial patterns containing irrelevant information was related to self-reported inattentive and hyperactive concerns. The study also found that differences in pattern learning among those with high and low self-reported inattentive and hyperactive concerns could be reversed by visually enhancing the distinguishing features of the irrelevant stimuli (e.g., making them a different color on the screen).

Finally, sequence learning tasks can also be helpful in elucidating specific impairments in diseases such as Huntington's disease and Parkinson's disease (Willingham 1998). For example, patients affected by Huntington's disease as well as those affected by Parkinson's disease show impairment on a serial response time task when the elements of the non-rule-based sequences to be learned repeat versus appear randomly. In contrast, those affected by Alzheimer's disease do not. Results from patient populations such as these help to identify brain areas critically underpinning pattern learning phenomena.

## Biographic Background

Paul L. Vasey was born in Toronto, Canada, on January 30, 1966. He received his B.A. (Honours) from the University of Alberta in Edmonton (1989); his M.A. from Simon Fraser University in Burnaby, British Columbia (1991); and his Ph.D. from the Université de Montréal in Québec (1997). He conducted postdoctoral research at the Université de Montréal and Concordia University in Montréal, and at York University in Toronto.

In 2000, Dr. Vasey accepted a tenure-track position in Psychology at the University of Lethbridge, Alberta, Canada. He was promoted to

Associate Professor in 2005 and to Full Professor in 2010. In 2015, he was awarded a Board of Governors Research Chair in Culture, Organization and Society. Dr. Vasey is one of only a handful of researchers in Canada to receive simultaneous grants from all three federal funding councils (NSERC, SSHRC & CIHR). His Research has also been funded by various other agencies including: NIH, National Geographic and Sigma Xi. He serves as Associate Editor for the *Archives of Sexual Behavior*. His research has been the subject of various television documentaries (National Geographic, Discovery Channel) and has been reported on in hundreds of newspapers and magazines worldwide (*New York Times*, *The Economist*).

Dr. Vasey's research interest focuses on understanding the proximate and ultimate reasons as to why organisms engage in nonconceptive sexuality. For two decades (1992–2012), Dr. Vasey carried out long-term research on the development and evolution of female homosexual behavior in captive and free-ranging Japanese macaques (*Macaca fuscata*). His Japanese macaque fieldsites included Arashiyama (near Kyoto) and Minoo (near Osaka). Vasey's work demonstrated that female homosexual behavior in Japanese macaques is not used to facilitate adaptive social goals (Vasey 1996, 2004; Vasey et al. 1998). This evidence-based claim was a significant departure from most of the animal behavior literature, which typically framed same-sex mounting as a socio-sexual adaptation. Instead, Vasey claimed that in some species, same-sex sexual behavior was a neutral, evolutionary byproduct. He showed that during most same-sex mounts, female Japanese macaques stimulate their genitalia thereby obtaining immediate sexual reward (Vasey and Duckworth 2006). His research group demonstrated that females sometimes choose same-sex sexual partners because they prefer them over the available male alternatives, and in doing so debunked the notion that females engage in this behavior simply because they are unable to obtain a male mate (Vasey 1998; Leca et al. 2015). Vasey demonstrated that male and female Japanese macaques engage in *inter-sexual* competition for female sexual partners – a process of mate

acquisition that had never been explicitly described in the literature (Vasey 1998). Research by Vasey's group revealed that homosexual behavior develops more rapidly in female Japanese macaques than heterosexual behavior, probably because the former involves less risky interactions than the latter (Leca et al. 2015). His group also showed that female Japanese adopt arbitrary mount postures during same-sex mounts and these vary across populations (Leca et al. 2014). This suggests that the expression of female homosexual mounting in Japanese macaques is influenced, in part, by cultural factors (i.e., group specific social processes). Dr. Vasey's long-term research on Japanese macaques is among the most detailed study of homosexual behavior in a non-human species ever conducted.

## Peak Fertility

Pavĺína Opatová  
Institute of Vertebrate Biology, Czech Academy of Sciences, Brno, Czech Republic

## Synonyms

[Peak reproduction](#); [The peak day](#); [The peak of fertility](#)

## Definition

Peak fertility is broadly defined as the period when both females and males of sexually reproducing organisms are considered most fertile. In the majority of animal species, peak fertility is associated with increased neuroendocrine activity in the brain, as well as with increased secretion of sex hormones in the gonads, and strongly affects sexual behavior and cognition of the individual.

## Introduction

One of the most important processes in the life history of every single organism is reproduction. The ability to produce the next generation of offspring is called **fertility**. Across the animal kingdom, a tremendous variability of life histories, social and breeding systems, different mating strategies, and a great diversity of reproductive behaviors has been documented. All of these factors strongly influence reproductive processes and cycles of particular species including the crucial phase of **peak fertility** (Clutton-Brock 1988). In the vast majority of internal fertilizers, the peak of fertility is commonly considered as a very short period within the female reproductive cycle, usually several days prior to ovulation and the day on which ovulation takes place, when females are most sexually receptive to males. However, in a broader perspective, it can also be understood as a period of life (e.g., several weeks, months, or years, depending on the lifespan of the species) during which both females and males are the most fertile and productive. In this respect, reproductive senescence plays a very important role and generally has a negative effect on reproductive functions after reaching a critical age. Moreover, seasonal changes in the intensity of reproductive activity have been described in various taxa in which seasonal breeding has evolved. For instance, most animals living in a temperate zone reach their fertility peaks in a specific period of time during the year in contrast to tropical species, which usually show no such

pattern and breed rather continuously throughout the year (Chemineau et al. 2008; Willmer et al. 2005).

## The Role of Neuroendocrine Regulation

Reproductive cycles including fertility peaks are under hormonal control. In most animals, two main types of hormones are involved – **gonadotropins**, usually peptides secreted in a specific brain region which control gonadal functions, and **gonadal hormones** (often steroids), produced in female and male gonads, also known as the sex hormones which are, among others, integral for reproduction and development of secondary sexual characters in both sexes. From an evolutionary point of view, this principal regulatory pattern is highly conserved among both invertebrate and vertebrate taxa, although it is strongly modulated by the environment and species' specific life histories (Willmer et al. 2005).

Different phases of the female reproductive cycle with respect to peak fertility have been described mainly in vertebrates, and the most detailed understanding of the reproductive cycle and its hormonal regulation has been achieved in mammals including humans. For instance, in therian mammals (both marsupials and placentals), a recurring female reproductive cycle called **estrous** is present, where a complete reabsorption of the uterine lining takes place in case no conception has happened. On the other hand, in humans and their close relatives among the primates **menstrual cycles** occur, which is associated with shedding of the endometrium and bleeding through the vagina (menstruation) when no ovum has been fertilized. A key role in mammalian cycle control plays the **hypothalamic-pituitary axis**. A specific brain region, the hypothalamus, acts as a “pacemaker,” secreting gonadotropin releasing hormone (GnRH) in pulses, and thereby mediates the link between the individual and the environment (in response to, for example, changes in temperature, photoperiod or the social environment). GnRH stimulates secretion of follicle-stimulating hormone (FSH) and luteinizing hormone

(LH) from the anterior pituitary, which in turn affects ovarian function, oogenesis, and the ovulation process by stimulating the release of sex hormones – estrogens (e.g., estradiol) and progesterone – from ovaries.

In humans, the women's peak of fertility is restricted to the so-called “fertile window” (about 6 days before and during ovulation) and overlaps with a two-day peak of blood estradiol and LH (usually around the 14–15. day of the menstrual cycle called **the peak day**). However, the precise timing of the peak day within the menstrual cycle can be affected by various environmental effects, such as diet, nutrition intake, and stress, and therefore may vary individually. It is supposed that humans and a few other species, for example, orangutans, do not signal their peak receptivity around ovulation by any obvious external signs, a phenomenon called concealed ovulation, which is quite rare in nature (Mihm et al. 2011). More often females express various kinds of signals, such as release of pheromones or expressing the attractivity enhancing signals (for more information see the following subchapter).

Regarding the effect of age, a woman's fertility begins in puberty and peaks around her twenties, starting to decline slowly after this age, and eventually reaching a critical point at around 35 after which women's fertility declines dramatically (Treloar et al. 1967).

Humans as other species which possess menstrual cycles are able to mate during the whole cycle, while in many other species mating activity is restricted only to a specific time period. For example, in mammals undergoing estrous, females are sexually receptive to males (being “in heat”) only during estrous itself. Peak fertility in such species typically comes once per year (monoestrous, e.g., wolves), twice a year (diestrous, e.g., dogs) or several times during the year (polyestrous, e.g., cats). Season may also influence female peak fertility; however, this has been much better documented in males (Willmer et al. 2005).

In contrast to females, many male vertebrates produce sperm rather continuously or in prolonged periods throughout their lifetime, generally being able to reproduce much longer than

females. In mammals, spermatogenesis is initiated by LH secreted from the pituitary gland. LH is then bound to the Leydig cells in the testes and in response starts producing testosterone which plays a key role in the regulation of spermatogenesis. For the normal course of spermatogenesis, FSH is also crucial, for it affects another group of cells in the testes – the Sertoli cells – that makes the testicular cells responsive to testosterone.

The fertility peak in males is also affected by age. The process of reproductive senescence has a negative effect on spermatozoa with substantial evidence of decreased sperm quality (e.g., higher percentage of sperm abnormalities, negative effects of increased oxidative stress, DNA damage, lower sperm motility) in older males across many animal taxa including humans (Harris et al. 2011).

Seasonal changes in male reproductive activity have been demonstrated particularly in seasonal breeders, in which their fertility peaks at the same time when the peak of testosterone secretion occurs. During this time, spermatogenesis reaches its highest intensity and is often associated with increase in ejaculate volume, sperm concentration, and viability and, among others, might be accompanied by an increase in testis size (Chemineau et al. 2008).

## Peak Fertility and Behavior

Beside hormonal changes during peak fertility and its physiological consequences, an individual's behavior is also affected in a substantial way. In that respect, both females and males of many animal species have evolved countless **external sexual signals**, which provide information about reproductive readiness and willingness to mate.

For instance, many nonprimate female mammals, such as rodents or felines, perform so-called **lordosis behavior** when they are in heat, a characteristic posture during estrous and peak fertility that advertises female receptivity to males. In brown rats, which belongs, as other rodent, to the spontaneous ovulators producing ova

regularly, lordosis posture is regulated by the hypothalamic-pituitary system and overlaps with GnRH and LH peaks. Therefore, it allows precise timing of copulation in relation to ovulation. In contrast to this, most felines, for example, domestic cats, are rather reflex ovulators, which means they ovulate immediately in response to mating. This process is regulated by estrogen affecting the brain, particularly the hypothalamus, directly (Beach 1976).

However, in many other mammals, behavioral signals of female peak fertility are not as intense as in previous cases. For example, many female primates react in response to estrogen peak by being only a little more sexually active, but in addition to this, they use various **attractivity enhancing signals**. In many mammals, female signal their peak fertility through swelling often followed by redding of the vulva, and in some primates, an exaggerated form of this signal – **sex skins (sexual swellings)** – has evolved. Several species from the Old World monkeys (including, e.g., mangabeys, mandrills, geladas, baboons or macaques) and the apes (e.g., chimpanzees) possess sex skins, which increase the female attractivity to males. Interestingly, these structures are present more frequently in polyandrous species (i.e., in which females have two or more mates). However, in case species are breeding seasonally, they lack sex skins even if they live in a polyandrous mating system. Moreover, polygynandrous species (i.e., where both males and females have multiple copulation partners) possessing sex skins have longer mating periods and ovarian cycles than those without sex skins. Beside visual signs described above, for example, female rhesus macaques enhance their attractivity also through olfactory signals. During their peak fertility, the increased estrogen stimulates bacteria in the vaginal microbiome to produce odors that attract males (Lee 1999).

Chemical and olfactory signals, particularly **pheromones**, are widespread across the animal kingdom. In many terrestrial invertebrates, such as beetles or moths, pheromones often plays a key role in attraction between mates and are often associated with long-range chemical

communication. During periods of time when females are willing to mate, they release pheromones, in many cases, from abdominal glands, based on which males are supposed to find a way to their potential partner. Such males therefore display various kinds of olfactory structures that are meant to act as detectors, typically various forms of antennae. Pheromones are used as sexual signals also in most vertebrate taxa, from amphibians, through lizards and snakes, birds, to mammals. In more highly derived vertebrate clades (i.e., amniotes), a special male vomeronasal organ system has evolved for the detection of pheromones, sometimes called Jacobson's organ. Some species, such as felids or ungulates (including, e.g., horses, cattle, pigs, camels, or deer – usually both females and males), perform specific sexual behavior associated with pheromonal detection during reproduction – the so-called Flehmen response, during which an individual curls back its upper lip, inhales scents, with the nostrils usually closed, into the vomeronasal organ (Silva and Antunes 2017).

In any case, during phases of reproductive activity and peak fertility, male behavior is obviously also affected extensively and most often is regulated by the primary male sex hormone, testosterone. Males of many animal species display a fascinating range of courtship behavior, usually involving a wide range of sexually selected traits (e.g., colorful patches, various morphological structures) in invertebrates and vertebrates, as well as in both external and internal fertilizers. In addition to this, the increase of testosterone during reproductive phases is also linked to higher aggressiveness of males (towards potential competitors) and the increase in intensity of territorial behavior, which is in turn supposed to increase the probability of mating success of the individual male (Andersson 1994).

## Conclusion

Although peak fertility generally depends upon the genetic program encoded in the animal's reproductive machinery, the environment and its

dynamics also play a very important role. With regard to this, endocrine system and hormones are key in mediating links between genes and environments, strongly affecting animal's reproductive cycles and their behavior. Molecular and some physiological underpinnings of the regulation of reproductive cycles are often evolutionary conserved across animal taxa. However, there are substantial differences, e.g., in the length, frequency, or timing of reproductive cycles including peak fertility between species, as well as in various forms of sexual behaviors associated with it. Moreover, even within species, significant variability can be observed. Beside this, peak fertility might be influenced substantially by age and reproductive senescence of the individual. Furthermore, seasonal changes in peak fertility are very common in many species and often reflect environmental effects, in order to allow the animals the best timing for mating, for example, breeding in optimal temperature, maximizing offspring food availability or minimizing predation risk. Timing of gamete production and mating is therefore crucial for maximizing the offspring's survival and parental fitness and in principal requires a certain level of coordination and synchronization between partners, which is in animals usually mediated through various external signals being involved in various forms of sexual behavior.

## Peak Procedure

Ruth M. Colwill<sup>1</sup> and Peter D. Balsam<sup>2</sup>

<sup>1</sup>Brown University, Providence, RI, USA

<sup>2</sup>Barnard College, Columbia University and New York State Psychiatric Institute, New York, NY, USA

## Synonyms

Discrete trial fixed-interval schedule; Peak-interval (PI) procedure

## Definition

A technique used to study interval timing in which an event (typically food) becomes available for performance of a target response (operant tasks) or is delivered (Pavlovian tasks) after a fixed duration of time on standard (training) trials and is omitted on randomly interspersed longer duration peak (probe) trials.

## Introduction

Animals live in environments that change with time making their capacity to exploit the temporal aspects of their experiences critical for effective decision-making and survival in the wild. Activities such as foraging for food, avoiding predators, and finding prey all benefit from the ability to anticipate precisely when something will happen and for decisions to be based on estimates of the rate at which these things will be encountered. Studies of interval timing are generally concerned with the ability of animals to measure intervals in the range of seconds to minutes. The peak procedure is one of several methods such as the temporal bisection procedure that have been designed to examine this ability in the laboratory. It has been used to investigate interval timing in birds, fish, and mammals, including black-capped chickadees (*Parus atricapillus*), domestic hens, pigeons, ring doves, goldfish, mice, rats, common brushtail possums (*Trichosurus vulpecula*), and humans. Performance on the peak procedure has been leveraged to develop and evaluate theories of interval timing. Additionally, imaging and pharmacological studies have used the peak procedure to uncover the neural mechanisms of interval timing in normal populations and to understand their dysfunction in clinical populations.

## Procedures and Examples

The basic peak procedure involves two trial types: one to train the subject to anticipate an event once a particular interval has elapsed and one to assess the accuracy and precision of that interval timing.

On standard (training) trials in an operant version of the task using food reinforcement (e.g., Catania 1970; Roberts 1981), a stimulus is turned on and the first response the subject makes after an interval of fixed duration produces a food reward and turns off the stimulus. This trial type is identical to a fixed interval procedure. On peak (probe or extinction) trials, the stimulus is presented for a much longer period of time (typically 2–4 times the length of the fixed interval) and no food is available. Peak trials are intermixed with standard trials. How the rate or probability of responding changes over time is the primary measure used in these studies.

Aside from these two trial types, there is no agreed upon way to implement a peak procedure. External stimuli such as changes in overall illumination, the presentation of sounds (e.g., white noise or tones) or visual cues (e.g., color of response key), and insertion of the response lever have been used as signals to mark the start of the trial. The proportion of standard trials to peak trials has varied widely across studies as have the value of the intertrial interval (ITI) and the total number of trials in a session. Moreover, some studies extend the peak trial for a fixed duration, whereas others have varied its duration; some operant studies require a response to turn off the stimulus on peak trials, whereas others do not.

A study by Sargisson et al. (2016) using the common brushtail possum (*T. vulpecula*) provides an example of an operant peak procedure. On standard trials, a light was turned on and the first lever press after 15 s (or 30 s or 60 s) produced a food reward (3 s access to a mixture of flaked barley and cocoa puffs) and turned off the light. On peak trials, the light was turned on, and the first lever press after 45 s (or 90 s or 180 s) turned off the light. Pressing the lever on the peak trials never earned food reinforcement. Peak trials were pseudorandomly interspersed among standard trials in a ratio of 1:4 and the ITI was 6 s.

Preceding use of the operant peak procedure was a task devised by Bitterman (1964) to study the temporal aspects of Pavlovian conditioning in goldfish. As is the case with the operant version, there are two trial types in a Pavlovian peak

procedure. On standard (training) trials, the conditioned stimulus or CS is turned on, the unconditioned stimulus or US (e.g., food or electric shock) is delivered automatically after a fixed amount of time, and the CS is turned off. On peak (probe or extinction) trials, no US is delivered and the CS remains on for at least 2–4 times the length of the fixed duration. In rodent studies of Pavlovian conditioning, head entries into an aperture where the food US is delivered are often used to index conditioning. The Pavlovian peak procedure may prove useful for testing special populations like transgenic mice because it obviates the need to pretrain a target response such as lever pressing.

Although the majority of studies have used positive reinforcement such as food, a few studies using the Pavlovian peak procedure have employed an aversive stimulus (Bitterman 1964; Drew et al. 2005). In one study using goldfish (Drew et al. 2005), a visual CS (red light) was presented on standard trials for 5 s (or 15 s for some subjects) and terminated with the delivery of a shock US; on peak trials, the CS was presented for 45 s without shock. The ITI was 90 s. General activity was recorded throughout the trials using a mechanical transducer that converted water displacement into discrete pulses.

## Analysis and Interpretation of Response Times

The procedure for analyzing response times on peak trials is the same for both operant and Pavlovian peak procedures. If interval timing were perfect and the only factor contributing to performance, one might expect a single response to be made on peak trials at the time that the expected event became available on the standard trials. In practice, however, even after extensive training, there are still many responses: some occur early (before the fixed interval has elapsed), some occur late (after the fixed interval has elapsed) although the majority of responses occur around the end of that fixed interval and typically within 10% of the FI value (Catania 1970; Roberts 1981). Response data from peak trials are typically plotted in two

ways: by averaging data from many peak trials and by examining data from individual peak trials.

### Averaged Peak Trials

In Fig. 1, the column of left-hand graphs displays response rates plotted as a function of time

averaged across multiple peak trials for a range of FI values for three different species: FI 8 s, 12 s, and 21 s in humans; FI 30 s and 50 s in pigeons; and FI 30 s and 45 s in mice. These graphs show that the rate of responding increases as the time to food availability is approached and then decreases after

**Peak Procedure, Fig. 1** Plots of averaged peak trials for humans, pigeons, and mice (from Balsam et al. 2009, with permission) show the scalar property of interval timing on a peak procedure. The left-hand column shows mean response rate as a function of absolute time in the interval

and the right-hand column shows mean percentage of maximum response rate as a function of relative time in the interval. The superposition of the relative response rate distributions shows the scalar property

that interval is passed. The distribution of response rates is approximately Gaussian. The extent to which the peak rate coincides with the value of the fixed interval provides a measure of timing accuracy. In every graph, the peak rates are close to the fixed interval values. The spread of responding around the peaks, however, is not identical and provides a measure of timing precision.

A ubiquitous characteristic of interval timing is that animals including humans time shorter intervals more precisely than longer intervals. As shown in Fig. 1, after extensive training, the spread of responding around the peak is greater for the longest interval trained than for the shortest interval trained for all three species: humans, pigeons, and mice. Remarkably, when the response rates are expressed as a proportion of their peak rate, the curves superpose, appearing almost identical regardless of the interval being timed (see the column of right-hand graphs of Fig. 1). This superposition feature reveals the scalar property of timing, indicating that the rate of responding is a lawful function of the proportion of the timed interval. This scalar property of interval timing is an example of Weber's law and has been documented in birds, fish, and mammals. For example, in their study with goldfish, Drew et al. (2005) found a peak in conditioned activity at about the time of the expected shock and variability in the activity distribution that was scalar. Sargisson et al. (2016), in their study of interval timing in the possum, also found a peak in responding at the time of expected food reinforcement and support for scalar interval timing.

### Single Peak Trials

When data are aggregated over many peak trials, the variation in the start and stop times of responding gives rise to an approximately Gaussian distribution. However, examination of response times on individual peak trials reveals that their distribution is not, in fact, Gaussian. Sometimes the pattern of responding on individual peak trials is scalloped; but often, the animal switches from a low response rate to a high rate as the time of expected food availability approaches and then back to a low rate of responding after that time has passed. These low-high and high-low transitions do not occur at exactly the same time on each peak trial.

Three measures are commonly extracted from the response patterns on individual trials: the start time (transition from low to high), the stop time (transition from high to low), and the run time (duration of the high rate of responding). Cheng and Miceli (1996) used these statistics to compare scalar and connectionist models of timing performance, with results strongly favoring scalar models.

### Experimental Studies of the Peak Procedure

Research using the peak procedure has uncovered a number of intriguing features about interval timing. For example, studies have shown that rats and pigeons can time multiple intervals in the same session when each interval is signaled by a different stimulus (e.g., Guilhardi and Church 2005; Roberts 1981; Subramaniam and Kyonka 2019). Interestingly, when training occurs in blocks of several consecutive trials with the same interval, temporal performance may be controlled by temporal regularities across trials and not by the discrete stimuli that signal the specific intervals, an effect attributed to overshadowing (Nepomoceno et al. 2020). Several studies using a single interval have reported that multiple peaks may occur when the duration of the peak interval trial is especially long, a pattern suggestive of underlying oscillators.

Early studies found that dopamine agonists such as methamphetamine shifted the peak of responding earlier (leftwards) suggesting an increase in the speed of the internal clock, whereas dopamine antagonists such as haloperidol shifted the peak of responding later (rightwards) suggesting a decrease in clock speed. Such pharmacological findings led researchers to propose a dopamine-driven internal clock. Manipulations of motivational parameters have also been found to affect timing in a similar way. For example, the peak of responding is shifted earlier (leftwards) when food value increases and later (rightwards) when food value decreases (Galtress and Kirkpatrick 2009). Collectively, these and other results have spurred efforts to reconcile the influence of dopamine on interval timing with

mounting evidence that dopamine activity encodes a reward or generalized prediction error (Balci et al. 2008) and to consider more broadly the relationship between temporal cognition and motivational variables.

There is currently no consensus on how animals accomplish interval timing. Behavioral data from the peak procedure have tended to favor Gibbon's (1977) scalar expectancy theory (SET) although they are to a large extent consistent with Machado's (1997) learning to time (LeT) model. fMRI studies support the involvement of fronto-striatal circuitry in human interval timing, and researchers have discovered a previously unknown set of neurons in the medial entorhinal cortex that turn on like a clock when an animal is waiting. The occurrence of commonalities in interval timing across diverse species suggests the potential for a common evolutionary mechanism for temporal processing. So far, the evidence does not point to a central clock for interval timing as there is for circadian timing. This suggests that timing arises from fundamental properties of neurons or networks.

## Conclusion

The peak procedure is a powerful tool that provides two measures of a subject's timing ability: an estimate of the expected time of reinforcement (the peak time) and the accuracy of that estimate (the peak spread). Analysis of individual and averaged response times has yielded evidence that, for a wide variety of species, interval timing is more precise with shorter than longer intervals. Data from the peak procedure have been influential in shaping and evaluating theories of interval timing and have tended to favor SET.

[Dominance hierarchy](#); [Ordinal position](#); [Social hierarchy](#)

## Definition

A hierarchical system of social organization in chickens.

Schjelderup-Ebbe (1922) was the first to recognize chickens have a stable pecking order (i.e., dominance hierarchy). Individual differences (e.g., body weight, comb size, etc.) and social experience play an important role in the establishment and maintenance of the hierarchy (Chase 1980; Cloutier and Newberry 2000). For example, Murchison (1935) assessed the ability of 16 roosters to maintain their hierarchy in a novel social setting. The roosters were ranked using dyadic encounters in which two individuals were simultaneously released from opposite ends of a runway and the distance travelled was used to determine the dominance relationship. The dominance-subordinate relationship determined from these dyadic encounters correlated strongly with the rank established in their natural environment (Murchison 1935).

The consistency of dominance relationships across settings suggests that chickens are able to recognize others. Indeed, individual recognition is crucial to the formation and maintenance of a stable hierarchy (Croney and Newberry 2007). Basic social discrimination has been assessed using a variety of different paradigms. For example, Murchison (1935) placed hens on a runway with a dominant individual caged on one side and a subordinate individual on the other (Murchison 1935). All group members apart from the highest and lowest ranking individuals showed a strong preference for the subordinate hen. To assess the limits of this ability, Ryan and Lea (1994) assessed the ability of chickens to discriminate between slides, video clips, and models of conspecifics. With each stimulus type, the birds were trained to discriminate between pairs of stimuli depicting two different birds. Chickens successfully discriminated between different conspecifics across all stimulus types.

The formation of the hierarchy goes beyond a mere representation of individual conspecifics, as relations between individuals must also be represented. A triad of hens is the smallest social unit in which a hierarchy can be established (Doyen 1987). An important property of linear hierarchies is that all their component triads are transitive such that, given A dominates B ( $A > B$ ) and B dominates C ( $B > C$ ), then A must also

dominate C ( $A > C$ ). Chase (1980) assessed the outcome of groups of three unfamiliar chickens when simultaneously placed in a neutral cage. With three individuals, there are four possible sequences in which the first two dominance relationships may be established. In the first relationship, individual A dominates B, with the bystander C observing the interaction. After this initial relationship is formed, (1) the initial dominant A can dominate the bystander C (double dominance), (2) the bystander C can dominate the initial subordinate B (double submissive), (3) the bystander C can dominate the initial dominant, or (4) the initial subordinate can dominate the bystander. While the first two outcomes guarantee transitive triads irrespective of the direction of the third relationship, the later two can result in either a transitive or intransitive triad.

To assess whether sequences that guarantee transitivity were more common than those that did not, Chase (1980) placed three hens in a neutral pen and observed the establishment of the hierarchy. The double dominance and double submissive patterns that guarantee transitivity were the only patterns observed. This finding is significant as the probability of a transitive triad forming is only 75% in animals meeting for the first time and having an equal chance of winning or losing (Zayan and Vaclair 1998). In a manipulation of his early experiment Chase (1985) and had the three individuals meeting each other in a series of paired encounters. Many of the encounters resulted in the formation of an intransitive or circular triad, for example,  $A > B$ ,  $B > C$ , and  $C > A$  (Chase 1985). This suggests the presence of the bystander (i.e., the bird that observes an aggressive interaction) may influence how the hierarchy is formed.

What information could a bystander gain by watching two birds interact? At a basic level, the bystander could gain information about each individual's fighting ability. More interestingly, the bystander could glean information about the relationship between the two individuals (Barnard and Burk 1979; Cloutier et al. 1996; Cloutier and Newberry 2000). For example, if the bystander watches a bird that is dominant to it being defeated by a stranger, the bystander could

use this information to submit to the stranger and avoiding the potential costs of fighting. This would be a form of social inference, where individuals settle a dominance relationship without conflict (Cloutier et al. 1996; Cloutier and Newberry 2000).

Assessing this experimentally, Hogue et al. (1996) staged a series of encounters in which a bystander (B) observed its former dominant (A) interacting with a stranger (C). Three different encounters were staged with the bystander observing (1) A being defeated by C ( $C > A$ ), (2) C being defeated by A ( $A > C$ ), and (3) two unfamiliar hens settling dominance. Following the observation, the bystander joined the other individuals in the enclosure. If the bystander was able to infer relationships from these observations, then they should respond differently under the first and second scenarios. Fittingly, bystanders that observed their former dominant being defeated by a stranger always submitted to the stranger (Hogue et al. 1996). In contrast, when its former dominant defeated the stranger, the bystander attacked the stranger in 50% of the group interactions (Hogue et al. 1996). In the final condition in which the bystander had no information on the direction of the relationship between A and C, C was avoided on 66% of occasions suggesting indifference toward the stranger (Hogue et al. 1996). The behavior displayed by the bystander under the three conditions demonstrates the hens were able to predict the likely outcome of their interaction with the stranger (Hogue et al. 1996).

## Conclusion

From the early observations by Schjelderup-Ebbe (1922) to the work by Hogue et al. (1996), our understanding of the cognitive operations that underlie the pecking order has grown substantially. More recently, Chase and Lindquist (2016) have argued pecking orders may be dynamic rather than static, suggesting there is still much to learn about how chickens determine who rules the roost and how long they may rule it for.

## Pederasty

Andrew Lear

Independent scholar, Watertown, MA, USA

The term "pederasty" derives from the ancient Greek "paiderastia," meaning "the love of boys." In both Greek and English, it refers to the erotic relations between adult men and pubescent/adolescent boys that were customary in ancient Greek culture. Similar customs have been typical of several other cultures (e.g., ancient Rome, Edo-period Japan). These cultures have generally approved of pederastic relations but disapproved of homosexual relations between adult males. The comparison of ancient Greek pederasty and modern homosexuality led to the development of the theory of social constructionism, now widely accepted in the Humanities and Social Sciences, that views concepts and practices of sexuality as variable over time and culture (Foucault 1985).

Pederasty is distinguished from the modern term/concept "pedophilia," which refers to an individual's tendency to desire sexual relations with children. "Pedophilia" refers to a drive in an individual, without regard for (or contrary to) social convention. The subject of desire can be either male or female, as can the object; conceptually, it refers to desire for prepubescent and pubescent children. "Pederasty" refers instead to a social custom. Participation was very broad and need not have indicated any particular type of desire or psychology, although some speakers (in poetry in particular) represent themselves as habitual and enthusiastic participants. "Pederasty" could only be practiced by males, and it did not include sexual relations with prepubescent children, but only pubescent/adolescent youths. Finally, "pedophilia" is generally thought of as a sexual desire, while the pederastic relationship is often presented in Greek sources of evidence as focused on mentoring and role-modeling more than sex. It was strongly associated with the activities (hunting, athletics, warfare, the symposium) and virtues (courage, loyalty, temperance) comprising the Greek masculine ideal; it was thought

of as the method by which this ideal was passed on from one generation to the next (Lear 2014).

Greek pederasty was regarded by both Greeks and non-Greeks in the ancient world as a defining characteristic of Greek culture (along with the associated practice of nude athletics). It is widely referenced in Greek literature, in particular in lyric poetry, comedy, and philosophy (Hubbard 2003); pederastic courtship is also a common theme in the artistic genre of vase-painting (Lear and Cantarella 2008), and nude male Greek statuary is imbued with the pederastic ethos. This custom does not appear in its developed form in the Homeric epics and seems therefore to have developed later, in the Greek Dark Ages or early Archaic period; from that point on, however, it seems to have been practiced throughout the Greek world (including, e.g., Southern Italy and Sicily, Alexandria, Syria) until the end of pagan Antiquity. It is associated with the elite, as it was associated with ideals, but it seems likely to have been practiced by a broad segment of society.

Greek pederasty (or at least the fact that Greek culture approved of some form of same-sex relations) is well known in the modern world. It is less widely known that erotic relations between adult and pubescent/adolescent males are or were considered acceptable or normative in many other cultures as well. The sexual relations that take place between initiator and initiand during adolescent initiation rituals in certain tribes on/near New Guinea are often compared to Greek pederasty (Herdt 1984), as they too imply a view of pederastic relations as contributing to the younger partner's maturation in a positive way. Several subcultures in premodern Japan were also associated with adult-adolescent male-male erotic relations; those between samurai and their pages had associations with military virtues similar to those of Greek pederasty (Leupp 1995). Other cultures on the other hand have practiced such relations without a marked pedagogical element. In ancient Roman culture, for instance, while pubescent/adolescent male youths were an acceptable sex object for adult males, these relations were not regarded as pedagogical. Thus, these relations are presented differently in Greek and Roman literary sources. Greek sources present the tan, athletic, markedly masculine youth as the ideal

love object and generally present these relations as intralite; they stress the youth's decisional role in the relationship. In Rome, by contrast, sex with a citizen boy would have constituted the crime of *stuprum*; Roman sources present the "effeminate" slave boy as the ideal object of pederastic desire (Williams 2010). The contrast in reported sexual practices underlines this distinction. In both cultures, anal sex was regarded as degrading for the penetrated partner. As a result, in Greek culture, pederastic relations are rarely presented as involving anal sex; even when, in comedy or invective, the possibility of anal sex is alluded to, the allusion is generally oblique. In Rome, pederastic sex is frequently presented as anal. Pederastic relations were also acceptable in earlier periods of Chinese history; the pederastic relations of early, semi-legendary emperors served as examples of this "love of the cut sleeve," but these relations are not presented as pedagogical. Classical Arabic and Ottoman literature and art also present pederastic relations/desires in a positive light, but without any association with pedagogy (El-Rouayheb 2005). The Bacha Bazi dancers of modern Afghanistan represent a related tradition. Pederastic relations were also regarded as acceptable in some milieus in the European Renaissance. Italian court records indicate that such relations were common (Rocke 1996); they are also an important theme in Renaissance Italian art, where many important artists produced works with clear pederastic implications and in several cases are also thought/rumored to have had pederastic relations (Donatello, Boccaccio, Leonardo, Michelangelo, Pontormo, Bronzino, Caravaggio, etc.). Pederastic relations are also an important theme in English Renaissance literature, particularly in Marlowe (*Hero and Leander*, *Edward II*) and in Shakespeare's Sonnets. It is difficult to reconcile this evidence with the strong injunctions against same-sex love in church and state law in both Muslim and Christian countries of this period, but it seems possible that there was a permissive counter-ideology among classically educated elites.

In fact, there is much more evidence in history for pederastic desires and relations than for the same-age homosexual relations among adults considered acceptable in the modern

West. In the cultures in which pederastic relations are practiced, adult-adult male-male relations are generally the objects of social disapproval. In both Greek and Latin, for instance, there are terms of reproach/ridicule for adult males who are penetrated sexually by other males: principally *katapugon* and *kinaidos* in Greek, *cinaedus* and *pathicus* in Latin. *Kinaidos/cinaedus* is etymologically obscure, but *katapugon* (down-the-anus) and *pathicus* (one who habitually submits to abuse) make clear that the disapproved practice of anal intercourse was considered typical of adult-adult male-male relations. Boys of the appropriate age for pederastic relations are generally not referred to with these terms. Pederastic relations were or could be considered an acceptable kind of erotic relations. In both cultures, there were forms of pederastic relation which were considered blameworthy (prostitution in Greek culture, *stuprum* in Roman). They could however be practiced appropriately, and in both cultures, the appropriate kind of pederastic relation was culturally emphasized. On the whole, attractions to women and boys were considered appropriate and normal to any man, rather than to specific types of men. A man could be seen as having a preference for boys over women (or the reverse), but this preference was not considered necessarily exclusive or defining. Adult-adult male-male relations on the other hand were considered inappropriate, and they marked at least the penetrated partner as a type of person subject to blame/ridicule. Interestingly, adulterers (which in these cultures does not mean merely a man who has extra-marital sex, but specifically a man who has sex with the wife of another man) were also seen as effeminate/degenerate. In fact, the *kinaidos/cinaedus* is at times accused of adultery in addition to his same-sex relations. Thus, these cultures did not divide activities or people into categories of heterosexual or homosexual (Halperin 1990). Pederastic relations were of course homosexual, but the people involved in them cannot be considered through an essentialist lens as homosexuals, any more than they can be seen as pedophiles. Instead, they must be seen as participants in a set of sexual customs/concepts different from modern Western ones.

## Introduction

Pedigree is a pictorial representation of the genotype or phenotype of an organism and its family

and ancestors (Griffiths et al. 1999). Pedigree is derived from the French words *pe de grue* which means the crane's foot, because the typical lines and split lines resemble the thin legs of a crane.

To study genetics, researchers trace the relevant characteristic trait in the families that are affected and their multiple generations and analyze it through pedigree chart. Pedigree helps to infer the mode of inheritance of the trait and thus helps in predicting the probability of transmitting the trait to future generation (Schaefer and Thompson 2014; Connor 2001).

### How to Construct a Pedigree?

A pedigree is an orderly presentation of family information. Human nomenclature is followed for pedigree for all species. After collecting information about the trait in the family, a pedigree can be made using standard pedigree symbols (see Table 1). Siblings should be mentioned in the order of birth, oldest to youngest. It is important to take a detailed history of the family including the stillbirths, pregnancy losses, consanguinity, genetic testing results, and cause of death. As this information is drawn based on the information facts given by the family, there is possibility for recollection errors.

Error in data entry or an inconsistent data will affect the downstream genetic analysis. There are tools and software to edit and check for Mendelian inconsistencies when information obtained through pedigree is not consistent with the genotype information.

### Pedigree Patterns

There are different modes of Mendelian inheritance and rarely some disease can have more than one pattern of inheritance. Patterns of inheritance can be autosomal dominant (in which an affected individual has one copy of a mutant gene and one normal gene on a pair of autosomal chromosomes), autosomal recessive (the affected individual has two copies of the mutant gene), X-linked (a mutation in a gene on the X chromosome), Y-linked (mutation

of genes in Y chromosome), and mitochondrial (mutation of and sporadic mode of transmittance).

Figure 2 shows autosomal dominance inheritance pattern. The key points are:

1. There are no skips, i.e., all the generations have the disease.
2. Both males and females have equal chances of having the disease.
3. An affected individual has equal chances of having affected and unaffected offspring.
4. Examples include *Marfan syndrome* and *neurofibromatosis type 1*.

Figure 3 shows autosomal recessive inheritance pattern. The key points are:

1. It might show skipping of generations, i.e., a phenotypically normal individual might have diseased babies.
2. Males and females are equally affected.
3. Both the parents must have the disease trait to transmit disease to the offspring.
4. Examples include sickle cell anemia and cystic fibrosis.

Figure 4 shows X-linked recessive disease. The key points are:

1. Only males are affected (affected females usually die intrauterine because of disease severity).
2. There is no skipping of generations.
3. A heterozygote mother transfers the disease to half the sons.
4. Examples include hemophilia and red-green color blindness.

Figure 5 shows X-linked dominant disease. The key features are:

1. Both males and females are affected.
2. Sons inherit disease only from mothers.
3. Daughters can inherit disease from mother and father.
4. Males are generally more severely affected than heterozygote females.
5. Examples include Rett syndrome and vitamin D-resistant rickets.

**Pedigree, Table 1** Standard pedigree symbols and terms representation in humans

Male 

Female 

Mating 

Parents and children (in order of birth), 1 boy and one girl

Dizygotic (nonidentical) twins

Monozygotic (identical) twins

Unspecified sex

Affected individual

Carrier of sex linked recessive

Death

Number of children

Abortion or stillbirth

Propositus

Consanguineous marriage

Proband (P)- First affected member who seeks the physician. Male affected in second generation is shown as P in the model pedigree given in Fig. 1

Figure 6 shows Y-linked disorders. The key points are:

1. Only males are affected.
2. There is no skipping of generations.
3. Example – male pattern baldness.

**Pedigree, Fig. 1** Representation of proband (P) in a pedigree

Figure 7 shows mitochondrial inheritance. The key points are:

1. Only mothers transmit the disease.
2. All the offsprings are affected.
3. Examples – Leber’s hereditary optic neuropathy (LHON) and mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS).

**Sporadic Inheritance**

Some inheritable diseases may involve multiple genes and complex inheritance. Environmental factors and sporadic mutations play a major role in the pathogenesis, e.g., retinitis pigmentosa.

**Pedigree, Fig. 4** X-linked recessive inheritance

**Pedigree, Fig. 5** X-linked dominant inheritance

**Pedigree, Fig. 6** Y-linked inheritance

**Pedigree, Fig. 7** Mitochondrial disorders

## Advantages of Pedigree Chart

Properly constructed pedigree helps us to know the mode of inheritance of a disease in any species where controlled matings are impossible. Using the knowledge of Mendelian inheritance and basic concepts of probability by applying the product and sum rule, geneticists can calculate the probability of the trait among future offspring of the families at risk. It is useful in genetic counseling during prenatal diagnosis and research and in animal breeding (Rubin et al. 1983).

## Summary

Pedigree charts are a systematic, comprehensive representation that summarizes a phenotype/genotype in a family and their ancestors. It is useful in studying the genetics of inherited diseases, including mode of inheritance, and helps in predicting the probability of outcome in future generations.

### Life History

Penguins (Aves, Sphenisciformes, Spheniscidae) are a family of seabirds that have evolved to swim and have lost the ability to fly about 60 million years ago (Williams 1995). Adapted to life underwater, penguins have developed strong hard flippers, with fused bones for fast propulsion when swimming. Their feathers are more abundant, dense, and miniaturized compared to other birds. These feathers are hard and stiff with a flattened shaft that overlaps, to provide insulation and waterproofing. Penguins have heavy, solid bones, as they lost the pneumatization of their bones, which was developed by flying birds to keep as light as possible and would be a disadvantage for penguins, increasing their buoyancy. All penguin species have the classic black-and-white “tuxedo,” a countershading assumed to serve as camouflage and helps disguise them from both prey and predators at sea: their dark back color helps blend in with the dark of the ocean floor, and the white of the belly blends with the light of the sun when seen from below. Their streamlined body is adapted for life in the water but is poorly designed for moving on land, which makes them waddle comically. This stance and gait has, however, generated much fondness from humans to these special birds,

and this charisma makes them excellent ambassadors for marine conservation.

The family is divided into 6 genera and 18 species, all restricted to the Southern Hemisphere (Williams 1995; Fig. 1). The genus *Aptenodytes* includes the largest penguins: the king (*A. patagonicus*) and emperor (*A. forsteri*) penguins. The genus *Pygoscelis*, or brush-tailed penguins, is composed of three species: the Adélie (*P. adeliae*), chinstrap (*P. antarctica*), and Gentoo (*P. papua*) penguins, all of which have a circumpolar distribution. The genus *Megadyptes* has only one species, the yellow-eyed penguin (*M. antipodes*), only found on New Zealand islands. The genus *Eudyptes* consists of crested penguins: the rockhopper penguins, which are divided into two species, the southern *E. chrysocome* and northern rockhopper (*E. moseleyi*); the erect-crested penguin (*E. sclateri*) only found on the Bounty and Antipodes Islands southeast of New Zealand; the Fiordland penguin (*E. pachyrhynchus*) restricted to New Zealand; the Snares penguin (*E. robustus*) breeding only on the Snares archipelago south of New Zealand; and the macaroni penguin (*E. chrysolophus*) closely related to royal penguin (*P. schlegeli*), with a circumpolar distribution. The genus *Spheniscus* includes the banded penguins: the African penguin (*S. demersus*), endemic to Southern Africa; the Magellanic (*S. magellanicus*) and Humboldt (*S. humboldti*) penguins breeding in South America and on the Falklands/Malvinas for the Magellanic penguin; and the Galápagos penguin (*S. mendiculus*) confined to the Galápagos Archipelago. Finally, the genus *Eudyptula* is monotypic, with the little or blue penguin, *E. minor*, found in Australia and New Zealand.

### Breeding Ecology

Penguins are typical K-selected species, characterized by small clutches, intensive parental care, late sexual maturity, and long life expectancy. Beside *Aptenodytes* penguins whom lay a single egg incubated on their feet, all other penguin species lay a clutch of two in a nest. Crested

**Penguins: Behavioral Ecology and Vocal Communication, Fig. 1** Classification of the 18 extant species of penguins (© Barbara Harmon, extracted from Ksepka and Ando 2011)

penguins lay asymmetrical eggs, with the second egg laid, the B-egg, systematically larger than the first laid egg, the A-egg, particularly so in erect-crested penguins where B-eggs are up to 85% larger than A-eggs (García Borboroglu and Boersma 2013). It was long believed that no *Eudyptes* penguins could raise two chicks, but recent evidences showed otherwise for southern rockhoppers in the Falklands/Malvinas (Poisbleau et al. 2008). This asymmetry in egg size favors the survival of the large B-egg and results in facultative brood reduction, a mechanism that increases reproductive output during years of particularly high food abundance (Williams 1995).

Incubation and chick-rearing duties are generally shared between sexes, although not systematically equal and the patterns vary among species. For example, in both *Aptenodytes* species, incubation is a male-only duty, while in crested penguins, females undertake the provisioning of the chicks for the first few weeks after hatching, while males guard the nest. Beside this marked pattern, more detailed analyses revealed a tendency for females to invest more in their current reproduction (e.g., Spelt and Pichegru 2017),

which partially explain the observed tendency for higher mortality of female penguins (Pichegru and Parsons 2014).

The breeding season lasts approximately 3–4 months for most penguin species, although slightly longer for Antarctic breeding birds (4–5 months), and is particularly long for the large penguins (8–9 months for emperors and up to 14 months for kings). The season is fairly synchronized for each species, except for banded penguins, where conditions in more temperate waters vary more widely across years. Therefore, their breeding season is more protracted and pairs sometimes raising two clutches within a year. For example, Galápagos penguins breeding in a relatively unpredictable environment can lay two to three clutches every year, and their success and breeding depend on food availability (i.e., upwelling; García Borboroglu and Boersma 2013).

After the breeding season, all penguins spend time at sea to increase their fat reserves, nearly doubling their weight, before their molt to replace feathers wearing with age. Penguins undergo a “catastrophic molt,” where all feathers are replaced at once, a phenomenon unique in birds.

Molting implies fasting due to total loss of insulation. Therefore, if the birds have not gained enough weight before molting, they will die. This molt period lasts 3–4 weeks, being slightly shorter for adults than for juveniles and slightly longer for large penguin species (García Borboroglu and Boersma 2013). The synchronization in molt is generally greater compared with breeding patterns, strongly associated with seasonality and peak food abundance in the environment. As a consequence, adults of some species like Adélie or African penguins are sometimes forced to desert their chicks to fatten up for molt (e.g., Woolfaardt et al. 2009). These observations suggest that molt could be a key driver of the penguins' annual cycle.

## Foraging Ecology

Penguin's diet varies relatively widely across species, colonies, and years. Antarctic and sub-Antarctic penguins (*Aptenodytes*, *Pygoscelis*), as well as *Eudyptes* penguins, feed predominantly on krill (mostly *Euphausia superba* and *E. crystallorophias* to a lesser extent) and Myctophidae (i.e., lantern fish) or Antarctic silverfish (*Pleuragramma antarcticum*). Warmer-water penguins (*Spheniscus*, *Eudyptula*) and *Megadyptes* feed mostly on small pelagic fish (anchovy, sardine, or sprat). Various species of cephalopods are commonly found in all penguins' diet in smaller proportion, although they can sometimes constitute up to 85% of their diet at some colonies in some years, when preferred prey are absent (García Borboroglu and Boersma 2013).

With the development of animal-borne miniaturized electronic recorders, the understanding of at-sea behavior of penguins greatly improved in recent years. Being flightless, the cost of foraging is much higher for penguins than for flying seabirds, and swimming is slower than flying, so they are bound to forage in a more restricted area. This is particularly true during the breeding season when they are constrained to return regularly to their nests to relieve their partners during incubation or to feed their chicks.

The average swimming speed of penguins is fairly constant across genera (ca 2 m/s). To increase that pace to >3 m/s, penguins are capable of leaping above water (i.e., porpoising), which allows them to reduce the drag of the water while catching a breath. This behavior is more common in penguin species prone to predation when departing their colony, suggesting a predator avoidance benefit. However, traveling at the surface is also energetically costly due to increased drag, and larger penguins are less prone to porpoise than smaller ones.

All penguins are capable to dive at great depth (up to 550 m for emperor penguins), but most dive within the top 70 m of the sea, where the light allows them to catch their prey. Indeed, most penguins are visual diurnal foragers, and their foraging efficiency decreases when feeding at night. They may, however, use their olfactory sense to locate foraging patches (Wright et al. 2011). Dive depths vary with species size and sex, with larger species and males (often slightly larger than females in most penguins) diving deeper, following simple allometric rules. But dive depths also vary with diet, and penguins feeding on myctophids or krill tend to dive deeper (e.g., 40–90 m for large penguins and most crested penguins) than species feeding on pelagic fish (e.g., 20–40 m on average for banded penguins). Some like yellow-eyed penguins are almost exclusively benthic feeders in waters 40–120 m deep, while others like Galápagos penguins foraged mostly within 6 m depth in shallow inshore waters (García Borboroglu and Boersma 2013). Recent deployment of animal-borne video cameras increasingly shows evidences of group foraging in several penguin species, whereby they may improve their foraging efficiency (McInnes et al. [in press](#)).

Generally, foraging distance and trip durations are much larger during the incubation stage compared to chick-rearing (e.g., 100–200 km over up to 2 weeks and 20–50 km during 1–2 days trip for Magellanic penguins, respectively; García Borboroglu and Boersma 2013). Longer foraging trips imply longer fasting periods for the partner guarding the nest and are therefore more common for larger species. But these foraging ranges mostly vary with the location of the species

colonies in respect to the continental shelf or areas of productivity (e.g., polar frontal zone, upwelling cells). For example, Gentoo penguins breeding in Kerguelen on a colony facing the open sea foraged up to 40 km from their colony while incubating diving at 60 m depths on average, while birds breeding in colony located within a gulf foraged only 3–11 km from the shore and at 40 m depths (Lescroël and Bost 2005). These patterns were explained by their diet composed of krill in the gulf and of fish in the open ocean (Lescroël and Bost 2005).

Little is known of their distribution outside the breeding season, with a few species being equipped of satellite transmitters or geo-locator system (GLS), which by recording light at sunrise and sunset indicates the latitude and longitude at which the birds are located. Results suggest relatively large dispersal in species with a circumpolar distribution, although the distance covered may depend on the molting areas.

## Vocal Communication

### Vocal Apparatus

Bird calls are produced through the syrinx (King 1989). The syrinx is a two-part organ located at the base of the trachea, formed by modified skeletal elements that provide support for a complex series of vibrating membranes (generating the sound) and muscles (involved in the control of the air flow from the lungs and tension and position of the membranes). The anatomy of the syrinx varies largely across species and orders. Penguins (order: Sphenisciformes) have a rudimentary bronchial syrinx, formed by the flattened first portion of the bronchi and membranous connections to the base of the trachea (Zeek 1951). Vocalizations are generally uttered during exhalation of air (Favaro et al. 2014), although for selected call types, vocal production occurs also during air inhalation. For instance, in the little penguin (Miyazaki and Nakagawa 2015) inhalation and exhalation phases contribute equally to the total duration of mating vocalizations.

Macroscopically, penguin's upper vocal tract consists of the tracheal tube, larynx, glottis (corresponding to the opening of the larynx), oropharyngeal cavity, and beak. The trachea is made of imbricated cartilaginous rings covered anteriorly and laterally by muscles (Zeek 1951), and this anatomical configuration allows the trachea to be voluntarily contracted by the bird, making its length and diameter vary. Overall, the penguin trachea presents a single cavity in the rostral part, while in the caudal portion, it is divided into two pipes, formed by cartilaginous rings connected in the mid-dorsal and mid-ventral area by bone tissue. This particular anatomical configuration is named "double trachea" and has been reported also for other aquatic birds (e.g., some petrels, order: Procellariiformes) and marine mammals (e.g., dugong, *Dugong dugon*, and sea lions, family: Otariidae). However, the functional basis is not yet fully understood. Moreover, it is important to note that the length of the septum varies among penguin species. In the Antarctic penguins of the genus *Pygoscelis* (Lockner et al. 1976) and in other sub-Antarctic or tropical species for which data are available from the literature (i.e., the crested penguins and the yellow-eyed penguin; Hocken 2002), the division of the air pathways is limited to one third or two thirds of the length of the trachea, depending on the species. Figure 2 shows two silicon casts obtained from the vocal tracts of Gentoo and African adult penguins. Silicon impressions show that in the Gentoo penguin, the septum dividing the trachea disappears in the upper portion of the air pathway. By contrast, the trachea of the African penguin is divided by the septum until the laryngeal cavity. Finally, the septum is not present in some penguin species, such as the blue penguin (Hocken 2002). Lockner et al. (1976) also showed that in Antarctic penguins, the number of tracheal rings and percentage of contraction of the windpipe is highly species-specific.

### Vocal Repertoire

Over the last decades, the vocal repertoires of several penguin species have been studied using a variety of methodologies, ranging from basic descriptions of the calls heard in the field to

**Penguins: Behavioral Ecology and Vocal Communication, Fig. 2** Silicon casts of the vocal apparatus of a long-tailed Gentoo penguin (left) and African penguin (right). Arrows indicate where, in the two species, the tracheal bifurcation occurs (© Livio Favaro and Marco Gamba)

detailed acoustic analyses (Jouventin 1982; Favaro et al. 2014). Overall, although different names were given for the same vocalization across studies, adult penguin vocalizations can fit within the following general categorization:

- *Contact calls*, uttered by birds to maintain cohesion with the group or with the partner
- *Agonistic calls*, uttered during fights and in territorial defense
- *Display songs*, complex calls made of sequences of syllables which can be uttered by single birds (*ecstatic display songs*) or by pairs (*mutual display songs*)

Finally, vocalizations interpreted as begging calls (Favaro et al. 2014) have been described for nesting penguin chicks (*begging peep*) and juveniles that had fledged from their nests (*begging moan*).

### Vocal Individuality

Penguins are birds that forage at sea but breed in colonies on land (Williams 1995). Moreover, during the breeding season, penguins form stable pairs where both sex cooperate for several months to rear only one or two chicks (Williams 1995). In large colonies, partners or parents and chicks have to recognize each other when returning from foraging trips at sea, and vocalizations are an essential part of this process (Aubin and Jouventin 2002). The mechanisms used to encode individual identity information in vocalizations vary largely among species and according to their breeding ecology (Aubin and Jouventin 2002). For example, because emperor and king penguins do not build a nest and vocal signals have to propagate through high levels of background noise and obstacles (Aubin et al. 2000), both these species have evolved a very sophisticated vocal recognition system to localize and recognize a parent or a mate in large colonies (Aubin et al. 2000). In particular, because the syrinx of birds is a two-part organ, where independent sounds can be simultaneously produced by different sets of muscles and membranes at the right and left sides (Suthers 1990), non-nesting penguins have evolved the ability to use the beats generated by these two different signals (the two-voice system), together with temporal characteristics of calls (variations in frequency or amplitude with time), to recognize each other. By contrast, the identification of the caller in nesting penguins (e.g., Adélie or Gentoo penguin), which first locate the nest and then use vocalizations as a confirmation of the location cue, mostly occur with relatively simpler mechanisms, such as the pitch of the call and the relative energy content of the harmonics (Jouventin and Aubin 2002). In these latter species, where visual cues assist vocal recognition, penguins have evolved simpler vocal identification systems, mostly based on the frequency analysis of the spectral profile of the call and the temporal pattern of vocalizations (Jouventin and Aubin 2002; Searby et al. 2004).

Recently, the source-filter theory of mammal vocal production (Taylor and Reby 2010 and references therein) has emerged as the dominant theory to explain also the acoustic output of

avian vocalizations. According to this theory, bird calls are generated by vibrations of membranes in the syrinx (source, determining the fundamental frequency, “ $f_0$ ”) and are subsequently filtered by the supra-syringeal vocal tract (filter, resulting in amplified frequencies called “formants”). The most recent literature suggests that the source-filter theory could be used to study vocal individuality in non-nesting penguin calls. In particular, research directed toward the measurement of formant frequencies has shown that individual variation in morphology and size of the vocal apparatus could result in individual acoustic distinctiveness (Favaro et al. 2015, 2016).

### Acoustic Signatures for Species Recognition

In the early 1990s, a study performed by Thumser et al. (1996) attempted to assess taxonomic relationships among captive congeneric *Spheniscus* penguins by analyzing vocalizations uttered during the breeding season. The results showed that these species consistently differ in the acoustical structure of their ecstatic display songs and that African and Magellanic penguins are more similar to each other than the Humboldt penguin. The study also showed that these three species are distinct from the southern rockhopper penguin (*Eudyptes chrysocome*), which was classified as out-group. The relationships found among *Spheniscus* species were consistent with the allozyme phylogenies. Overall, the study by Thumser et al. (1996) was the first to support the hypothesis that penguin vocalizations encode species-specific information, suggesting that the amount of acoustic divergence is proportional to the genetic distance. These findings have been recently confirmed in *Spheniscus* penguins through more detailed acoustic analyses based on the source-filter theory approach (Favaro et al. 2016). However, it is still not clear whether species-specific information encoded in penguin calls can be perceived by heterospecifics. For instance, *Spheniscus* penguins of different species are known to readily hybridize when grouped together in captivity. Moreover, hybrids have been discovered also in wild settings, such as in the Chilean islands of Puñihuil and Metalqui

where *S. magellanicus* and *S. humboldti* overlap their geographical distribution along the coast of the Pacific Ocean.

Recently, the presence of acoustic divergence has been observed also in the little penguins, where the dominant frequency of advertising calls shows a slight shift between the two subspecies (*Eudyptula minor minor* and *E. m. iredalei*), which live in two different regions within New Zealand. In this case, further playback experiments also showed that females recognize and prefer their local male calls (Miyazaki and Nakagawa 2015).

### Hearing Abilities

Hearing in penguins has been investigated by means of evoked cochlear potentials in the African penguin (Wever et al. 1969). Overall, the best auditory sensitivity for this species was identified between 600 and 4000–5000 Hz. Sensitivity beyond 4000 Hz declined approximately 60 dB per octave, and 15,000 Hz was defined as the practical auditory limit. Furthermore, conditioning experiments on the emperor penguin (Jouventin et al. 1979) determined that this species can perceive sounds in a frequency range from 30 to 12,500 Hz, with a temporal resolution of sound perception of 15 ms (i.e., three times more accurate than human abilities). Overall, we can assume that penguins show a hearing sensitivity in air that fits with the values reported for the majority of birds, apart from a slightly higher upper limit compared to the other seabirds.

Penguins can also hear underwater sounds. They are responsive to vocalizations of marine predators, such as killer whale (*Orcinus orca*) calls (Frost et al. 1975), and are particularly sensitive to underwater blasting (Cooper 1983). African penguins also showed avoidance of underwater noises generating by seismic surveys within 100 km of their colony (Pichegru et al. n.d.). However, because hearing sensitivity in diving birds can differ from air to water, detailed measurements about the underwater hearing capabilities of penguins are needed. Results arising from this research would be useful to better understand the potential effects of the anthropogenic

noise on the auditory thresholds and vocal behavior of penguins, which frequently live in populated coastal regions (Thomas and Ksepka 2013), are potentially exposed to disturbance from tourism (Seddon and Ellenberg 2008), and feed at sea in high-traffic naval areas (García Borboroglu and Boersma 2013).

Threats and Conservation

Penguins are among the most threatened seabird families (Trathan et al. 2015), with 60% of the species classified as threatened (five endangered, six vulnerable) and another two as near threatened (Trathan et al. 2015). Most of their populations

**Penguins: Behavioral Ecology and Vocal Communication, Table 1** Penguin species population size, trends, threats and IUCN conservation status. Declining populations and endangered and vulnerable species have

bold red letters. For threats, the boxes are colored to indicate their impacts: red = major, orange = moderate, and yellow = minor

have declined since the 1970s, mirroring trends of a wider range of seabird taxa (Palecny et al. 2015). Threats are mainly from anthropogenic origin and shared across most genera (Table 1). Pollution from oil spills (chronic or catastrophic) can strongly affect penguins from temperate areas along tanker routes and alone has the potential to cause the extinction of little and African penguins (García Borboroglu and Boersma 2013). Introduced predators (mustelids, rats, cats) on islands devoid of mammalian predators have caused major damages on some colonies and may still be the most important factor affecting Fiordland penguin population change (García Borboroglu and Boersma 2013). Human disturbance from tourism, coastal development, change in land use, or road accidents can also seriously impact breeding success, increase basal stress levels, and reduce habitat available (e.g., Seddon and Ellenberg 2008). However, the major threats weighing on most penguins are the impact of fishing and climate change. Many penguins are vulnerable to bycatch in trawl or gill nets, in particular the banded penguins. Perhaps even more worrying, however, is the competition with industrial fisheries over the same resources, in particular for penguins targeting predominantly small pelagic fish or krill. Small pelagic fishing is the world largest fishing industry, removing up to 20 million tons of fish annually, mostly from the Benguela and Humboldt Current off the coasts of South Africa and Chile and Peru, respectively (FAO 2016). Krill fishing is also in rapid expansion in response to an increased demand for fish meal by the rapidly developing aquaculture industry (FAO 2016). Impact of resources competition with fisheries can be severe on seabird population (Cury et al. 2011), although clear evidences linking penguin population dynamics to reduced food resources from harvesting are still lacking (Trathan et al. 2015). Finally, climate change reduces breeding habitat and molting sites available for some Antarctic penguins, while heat waves or storms, which frequency is increasing, increase clutch and chick mortality in warmer-water species (García Borboroglu and Boersma 2013). Climate change incurs major ecosystem

shifts worldwide, often with unpredictable consequences on top predators like penguins. Ocean acidification due to increased concentrations of carbon dioxide in the oceans is predicted to reduce availability of calcium carbonate-dependent species, such as krill, on which many population of penguins depend tightly. Marine protected areas are developing across the world, potentially benefiting penguins (Pichegru et al. 2010), and eradication programs are underway on several penguin colonies. But marine pollution such as oil spills, habitat degradation on land, and fisheries impact, either from bycatch of penguins or from competition over the same resources, need to be addressed urgently.

## People for the Ethical Treatment of Animals (PETA)

Heather Rally

Captive Animal Law Enforcement, PETA Foundation, Norfolk, VA, USA

## Introduction

People for the Ethical Treatment of Animals (PETA) is the largest animal rights organization in the world, with more than 6.5 million members and supporters. The 501(c)(3) charity works through public education, cruelty investigations, research, animal rescue, legislation, special events, celebrity involvement, and protest campaigns. The group was founded in 1980 by Ingrid Newkirk and a small group of friends.

Headquartered in Norfolk, Virginia, with a West Coast office in Los Angeles, the organization has international affiliates in the United Kingdom, France, the Netherlands, Germany, India, Australia, and the Asia-Pacific region.

PETA focuses its attention on the four areas in which the largest numbers of animals suffer the most intensely for the longest periods of time: the food industry, the clothing trade, laboratories, and the entertainment industry. Its motto: “Animals are not ours to eat, wear, experiment on, use for entertainment, or abuse in any other way.”

In addition to these core issues, PETA campaigns against the cruelty of fishing, the killing of animals regarded as pests, and the keeping of chained backyard dogs, among many other issues.

PETA's Community Animal Project helps cats and dogs near its headquarters, in poorer areas of Virginia and North Carolina. In 2016, more than 15,000 dogs and cats were sterilized – including more than 1300 pit bulls – at low cost or for free.

More than 1000 dogs and cats were transported to and from the clinics, free of charge, for people with no transportation.

PETA's fleet of mobile clinics assists thousands of indigent families by providing free medical services, including repairing prolapsed organs, performing lifesaving surgeries on dogs suffering from dangerous uterine infections, removing tumors and ruptured growths, performing drainage surgery for hematomas and infected wounds, and treating ear, skin, and upper respiratory infections.

PETA also shelters neglected dogs and cats who are ill or injured and pursues justice in cruelty cases.

In 2016, PETA delivered more than 312 sturdy doghouses and more than 1900 bales of straw bedding to neglected "backyard dogs." The organization's program has given away nearly 6500 doghouses since its inception.

## The 1980s

PETA first caught the public's attention in the summer of 1981 during what became known as the "Silver Spring monkeys case," a widely publicized dispute about experiments conducted on 17 macaque monkeys inside the Institute for Behavioral Research in Silver Spring, Maryland. The case lasted 10 years and involved the only police raid on an animal laboratory in the United States. PETA's investigation resulted in the first conviction of an experimenter for animal abuse and the first withdrawal of federal research funds because of cruelty to animals. It was also the first animal-experimentation case ever heard by the US Supreme Court, which gave a unanimous, positive ruling.

PETA's demonstrations led to the closure of Arrow Live Poultry, the last remaining slaughterhouse in Washington, D.C.

PETA distributed an undercover video showing Las Vegas casino "entertainer" Bobby Berosini repeatedly punching, shaking, striking, and slapping the forcibly restrained orangutans he used in his casino act. He subsequently brought suit against PETA, claiming that it had defamed

him and invaded his privacy. In 1995, the Supreme Court of Nevada ruled that Berosini's lawsuit was without merit and ordered him to pay PETA's court costs. The US Department of the Interior revoked his captive-bred wildlife permit, making it illegal for him to buy or sell orangutans, and his animals were sent to sanctuaries.

PETA stopped a plan by Cedars-Sinai, California's largest hospital, to ship stray dogs from Mexico for experiments.

## The 1990s

PETA's "Rather Go Naked Than Wear Fur" campaign was launched on the streets of Tokyo outside a Japanese fur expo in 1992. The protest made headlines around the world and led to PETA's extensive and iconic naked celebrity ad series.

PETA's efforts led to the first-ever cruelty charges filed against a factory farmer for allowing tens of thousands of chickens to starve to death. The president of the company ultimately pleaded guilty.

PETA succeeded in getting Taiwan to pass its first-ever law against cruelty to animals, which prevented countless dogs from being beaten, starved, electrocuted, and drowned in the country's pounds.

PETA's undercover investigations into pig-breeding factory farms in North Carolina and Oklahoma revealed horrific conditions and abuse, including skinning a pig alive, leading to the first-ever felony indictments of farm workers. Three were convicted.

## 2000–2010

After a PETA campaign including more than 400 demonstrations at restaurants in more than 23 countries, as well as advertising and celebrity involvement, McDonald's became the first fast-food company to agree to make basic animal-welfare improvements for farmed animals.

Evidence submitted by PETA led to the mandatory relinquishment of all 16 elephants used by

the Hawthorn Corporation, an elephant-rental company.

PETA's investigation into Aviagen Turkeys, Inc., part of the self-proclaimed "world's leading poultry breeding company," revealed that workers tortured, mutilated, and maliciously killed turkeys. Three former employees were indicted on felony cruelty-to-animals charges – the first felony charges for abusing factory-farmed poultry in US history – and two became the first factory farmers to be convicted of abusing turkeys. One man was sentenced to a year in jail – the strongest penalty levied for abusing a factory-farmed animal in US history – and all three were barred from owning or living with animals for 5 years.

PETA's investigation into animal dealer US Global Exotics prompted the largest animal seizure in history – more than 26,000 animals. The owner fled the country to evade federal charges.

After intense PETA campaigning against horrific combat training exercises conducted by the Bolivian military – a video of which showed live dogs tied down, repeatedly stabbed, and screaming in agony – the country's Ministry of Defense ended the killing by issuing the military's first-ever animal-protection regulation, which "prohibit[s] all acts of violence, exploitation, [and] mistreatment that provokes the death of animals."

The European Chemicals Agency spared up to 4.5 million animals the agony of being used for toxicity testing in a massive EU program after receiving documentation provided by PETA scientists.

Just 1 week after PETA released the results of its shocking eyewitness investigation into Professional Laboratory and Research Services and filed a complaint with the US Department of Agriculture (USDA), the North Carolina-based contract animal-testing facility surrendered nearly 200 dogs and more than 50 cats and closed its doors. This was only the second time in US history that a laboratory was forced to surrender its animals and shut down.

Less than 6 months after PETA released its eyewitness investigation into laboratories at the University of Utah, legislators voted overwhelmingly to amend an archaic state law so that government-run animal shelters would no longer

be forced to sell dogs and cats to laboratories on demand.

In India, the PETA-supported charity Animal Rahat was founded. Its unique mission helps some of the most neglected animals in the world – bullocks, donkeys, and other working animals in India. This lifesaving program now offers services throughout three districts in Maharashtra, one of the largest states in India. Animal Rahat is run by a dedicated staff that includes veterinarians, veterinary assistants, animal caretakers, and a full-time community educator. All Animal Rahat veterinarians are on call for emergencies and advice around the clock, every day of the year.

## 2011–Present

The USDA fined Ringling Bros. and Barnum & Bailey Circus \$270,000 – the largest fine ever paid by an animal exhibitor – for violations of the Animal Welfare Act after PETA presented unequivocal evidence of animal abuse, including beatings, the negligent death of a lion, lame elephants forced to perform despite chronic pain, and a baby elephant who died during a training routine.

PETA blew the lid off Ringling Bros.' animal abuse when a whistleblower shared photographic evidence from the circus's training compound revealing that baby elephants are torn away from their mothers and subjected to violent training sessions so that they will learn how to perform tricks.

Citing a "dramatic drop" in ticket sales, in May 2017, Ringling Bros. and Barnum & Bailey Circus shut down after 146 years.

In the first case of its kind, PETA, three marine-mammal experts, and two former orca trainers filed a lawsuit asking a federal court to declare that five wild-caught orcas forced to perform at SeaWorld were being held as slaves in violation of the 13th Amendment to the US Constitution. The filing – the first ever seeking to apply the amendment to nonhuman animals – named the five orcas as plaintiffs and sought their release into their natural habitats or seaside sanctuaries.

After intensive campaigning by PETA, the US military ended the use of monkeys in the Army's cruel chemical-attack training course.

The US Coast Guard became the first branch of the military to suspend the shooting, stabbing, and killing of animals in trauma training drills. Calling these methods "abhorrent," the military service's commandant said that it would switch to non-animal training methods such as human patient simulators. It confirmed that the shift had come after an official review of its "live tissue training" prompted by a PETA exposé. In 2012, PETA had released disturbing video footage from a secret trauma training course for the service's personnel that showed instructors cutting the legs off semi-conscious goats with tree trimmers, stabbing them with scalpels, and pulling out their internal organs as they moaned and kicked.

The top ten advertising agencies in the United States – McCann Erickson, BBDO, Y&R, DDB, Ogilvy & Mather, TBWA, Draftfcb, Grey, JWT, and Campbell Ewald – all signed PETA's Great Ape Humane Pledge, banning the use of great apes in their advertising.

After PETA donated simulators to Egypt, it ended all use of animals for medical trauma training.

After 2 years of PETA campaigns and a lengthy lawsuit brought by PETA and local residents, the Supreme Court of Puerto Rico nixed a plan by the Bioculture Corporation to set up a primate-breeding facility there and sell monkeys to US laboratories.

Following PETA's investigations and campaign, a sweeping set of reforms – including limitations on whipping, increased drug testing, and mandatory on-site horse ambulances – was introduced and accepted by many horse-racing tracks.

After decades of conducting cruel experiments and just 6 months after PETA purchased stock in the company in order to introduce a shareholder resolution on animal testing, BIOQUAL announced that it would end its use of chimpanzees. Formerly known as SEMA, the facility was first exposed in 1986, when PETA released footage of chimpanzees locked inside tiny isolation chambers there.

After a 2-month PETA eyewitness investigation documented that thousands of animals were being neglected and dying and many more were being cruelly killed, law-enforcement officials raided Global Captive Breeders, a company in Lake Elsinore, California, that bred and sold reptiles and rats for the "pet" trade. This resulted in the largest rescue of neglected rats in US history and the largest seizure of animals, including more than 600 reptiles and 18,000 rats, ever in California. Local authorities charged the owner and manager with a total of 223 felony cruelty-to-animals and related charges.

PETA prevailed in a lawsuit against the US Fish and Wildlife Service for illegally issuing captive-bred wildlife permits, allowing it to keep a closer eye on animals bred in captivity, weigh in on permit applications, and bring legal challenges against permits that are improperly issued to animal-abusing facilities such as SeaWorld, Have Trunk Will Travel, and others.

Following decades of campaigning by PETA, the US Army announced that it would reduce its use of animals in deadly trauma training exercises and restrict training for many military personnel to exclusively nonanimal methods.

After hearing from PETA that many sheep used for their wool endure a painful procedure called "mulesing," in which large chunks of skin and flesh are cut from their backsides without any painkillers, more than 50 national and international clothing retailers, including Abercrombie & Fitch, Liz Claiborne, H&M, Kenneth Cole, Perry Ellis International, and Express, stated that they would use wool that comes only from non-mulesed sheep, as the industry begins to phase out the cruel practice.

PETA's exposé of Taiwan's pigeon-racing industry resulted in a national sweep of pigeon-racing clubs. Police confiscated cash and equipment and froze over \$4.5 million of apparent illegal gambling proceeds in two clubs' bank accounts.

The first-ever eyewitness investigation into the angora wool industry showed workers tying down screaming rabbits and ripping their fur out, leading to a ban on the sale of angora by more than

70 companies around the world including H&M, Calvin Klein, and Tommy Hilfiger.

The scientific and regulatory expertise of PETA and its affiliates was consolidated to form the PETA International Science Consortium Ltd., which, having been accepted as an accredited stakeholder in the agency that oversees the largest chemical-testing program in the world, works with industries, private research facilities, and governments to promote nonanimal tests worldwide.

*I, Chicken*, the first-ever empathy-building virtual reality experience – which allows people to view life from the perspective of a chicken being sent to slaughter – traveled to more than 150 universities across the United States, including Harvard, Stanford, Brown, Dartmouth, the University of Pennsylvania, and Princeton.

After intensive efforts led by PETA India and with scientific support from PETA USA and the PETA International Science Consortium Ltd., India officially banned the importation of animal-tested cosmetics. PETA India rallied support from scientists, ethical companies, celebrities, and leading government officials.

PETA launched a tour of its *I, Orca* empathy project, which uses wireless Google virtual reality goggles to immerse participants in a world in which they are free to swim in the ocean with their orca families. Users also meet an orca mother (voiced by *Nurse Jackie* star Edie Falco) who still mourns the baby who was taken from her decades ago and sent to SeaWorld, where he has been sentenced to a miserable life in captivity. PETA took *I, Orca* on tour to cities near all three SeaWorld parks.

Following a PETA exposé, the National Institutes of Health ended more than 50 years of infant-monkey maternal-separation studies.

PETA secured the first conviction for the production and distribution of disturbing “crush videos” after supplying evidence to law-enforcement officials in Houston and encouraging federal authorities to press charges against Ashley Nicole Richards for violating the Federal Animal Crush Video Prohibition Act of 2010.

PETA filed a groundbreaking lawsuit asking a US federal court to declare Naruto – a free-living crested macaque – the author and owner of the internationally famous “monkey selfie” photograph that he took using a photographer’s unattended camera. The aim is to get the court to declare a nonhuman animal an owner of property (the copyright of the photograph), rather than a piece of property.

After years of intense PETA-led campaigns, SeaWorld announced an end to its orca-breeding program, which means that the current generation of orcas imprisoned in SeaWorld’s tanks will be the last.

Following a PETA campaign that saw the end of year-long pesticide poisoning tests on dogs in 2007 in the United States and in 2013 in the European Union, PETA scientists succeeded in persuading the Canadian government to end this testing, thus preventing hundreds of dogs from being forced to eat pesticide-laced food or inhale pesticide fumes every day for a year before being killed and dissected. This occurred during the same year that PETA scientists’ work with the Environmental Protection Agency (EPA) and industry resulted in an EPA announcement that it intended to reduce and – ultimately – eliminate the use of animals in lethal pesticide toxicity testing.

In a landmark case following the release of a PETA exposé, at least 6 sheep shearers were charged with a minimum of 70 counts of cruelty to animals for the first time in history. The exposé documented that wool industry workers in Australia beat sheep in the face with electric clippers and punched and stomped on their heads and necks. The first five defendants pleaded guilty, and the sixth was found guilty.

Perception-action theory endeavors to understand and describe the relationship between animal and its environment. The essential question is: How does an animal perceive and interact with the environment it lives in? Right after being born, an animal starts constantly exploring and interacting with its environment via actions, and these behavioral interactions continue until its death. For instance, a human baby looks around his/her environment with deep curiosity and tries to reach and touch the objects that surround him/her to discover and learn about them and turns his/her head to the direction where sounds come from to understand what makes the sound. Likewise, a giraffe reaches to the leaves on the top of a tree to eat; a deer runs away from its predator to survive; you move your eyeballs (even maybe your head) to read this entry on the computer screen or paper that you are holding and slide the screen or turn the page when you reach the end of the screen or page. Actions are an intrinsic part of every animal's daily life. For example, while reading this entry, you may want to enjoy your coffee by taking a sip from it. In order to do this, you need to reach out and take grasp your coffee cup sitting on the table in front

of you. To be able to plan and perform this reaching out action, your brain has to know exact distance and direction of the coffee cup with respect to your position. As if this were not complex enough as it is, your brain also must plan how to grasp the coffee cup. Regarding the grasping plan, for example, your brain must know how the handle of the coffee cup is oriented in order to position your hand appropriately. This simplified example of reaching out to and grabbing a coffee cup to take a sip from your coffee illustrates perceptual requirements of planning and carrying out any task (action). Interestingly, however, not only it is the case that action depends on perception, but it is also true that perception depends on action. Turning back to the coffee cup example, you will need to move your eyes or move your head, or perhaps you may even need to lean in a specific direction to be able to gather the requisite perceptual information in order to assess the location, orientation, and dimensions of the coffee cup. In the words of James Gibson (1979), whose studies and approach give rise to insights of perception-action theory:

Locomotion is guided by visual perception. Not only does it depend on perception but perception depends on locomotion inasmuch as a moving point of observation is necessary for any adequate acquaintance with the environment. So we must perceive in order to move, but we must also move in order to perceive. (Gibson 1979, p. 223)

Perception-action theory came fore with Gibson's information-based approach. Traditional theories of perception treated perception as wholly a matter of sensation and the sensory organs of organisms. Gibson, however, was among the first to recognize that this sensation-based approach fell short of explaining and predicting animal perception and behavior. He asserted that perception is not sensation but information based (Gibson 1979).

The traditional sensation-based approach is rooted in the representational realism of Locke (Lombardo 1987) and Plato (Dotov et al. 2012). According to the sensation-based approach, perception is caused by stimulation on the sense organs and not necessarily requires any action prior to the perception. The registered sensory-

stimulation is processed by the central nervous system in order to simulate a three-dimensional model of the environment, and what we perceive is based on such simulations combined with past memories of our experiences through higher cognitive processes (Gibson 1950, 1966, 1979). For example, if you hear a noise from outside while reading these words, you most likely turn your head and look outside through window. Let's suppose you see a cat in a tree. The cat is only partly projected in your eyes because the branches and leaves of the tree and the frame of the window occlude the rest of the cat. Then, how do you perceive the cat as a cat? The sensation-based approach answers to such question as follows: right after this image is projected onto your retina, in which the cat is partly discernible, thus stimulating your optic nerve, your brain creates a mental image based on the visible parts of the cat and fills out the missing parts by retrieving something like the whole cat image from your past memories of the experiences. As a result, what you perceive is the representation of the cat, which is created in your mind, but not the cat itself. In this sense, we perceive not directly the real world but its representation constructed in our mind; perception is indirect that requires mediation of third parts. However Gibson rejects this sensation-based approach of indirect perception. As in his example, "... [Direct] perception is what one gets from seeing Niagara Falls, say, as distinguished from seeing a picture of it. The latter kind of perception is mediated. So when I assert that perception of the environment is direct, [ mean that it is not mediated by retinal pictures, neural pictures. or mental pictures. Direct perception is the activity of getting information from the ambient array of light" (Gibson 1979, p. 147).

According to the information-based approach, perception does not require any mediation of any constructed representation such as neural image, mental image, nor additional process such as past memories. Instead, perception is itself the activities of perceptual systems. Gibson differentiates the perceptual system from senses; the former one is active, whereas the latter is passive (Gibson 1979). The term perceptual system refers more than just sensation. Vision, for instance, involves

an active system that is not simply dependent on the sensation of a passive sense organ (retinal image). As Gibson indicated, “.. natural vision depends on the eyes in the head on a body supported by the ground...” (Gibson 1979, p. 1). Perception is the product of the actions on the part of the perceptual systems which require that information be gathered directly from the environment by means of looking, listening, touching, testing, and smelling. An animal can continuously act, gathering information throughout its life without reaching any limit and without storing it all in memory (Gibson 1979). Returning to the cat example, Gibson argues that there is no sensation of the occluded parts and perceiving it does not require the past memories attached to the present sense data. The information, which is defining the objects, textures, layouts, and surfaces in the environment and thus the occlusion, is picked up by vision, which is not sense organ but a perceptual system. In the Gibsonian nomenclature, the rich and continuous information source for vision is termed optic array. The structured light (also known as ambient light) reflecting from the environment and reaching the observer’s eyes constitute the optic array. The visual information can be derived from the optic array with respect to point of observation. When the point of observation changes, the visual information which is projecting on the eye also changes as an adjacent order over the time while moving. Yet, some invariants persist in the adjacent order of changing visual information. Such persistent invariants project the information about the continuing surfaces and layouts in the environment. On the other hand, changing the point of observation results in disturbance of the persisting invariants which is projecting the occluded surfaces and layouts; at the edge of any object, surfaces, and layouts that is occluding the background, either accretion of the occluded surface to or deletion of the occluded surface from the visual information occurs over the time in the optic array. Such accretion and deletion indicates the occluded surfaces. In the cat example, when you (the observer) change your perspective (point of observation) by moving or leaning, accretion and deletion series related to cat’s occluded

surface occurs over the time at the edges of the branches and leaves of the tree and the frame of the window; such deletion and accretion series specify the occluded surface of the cat. The optic array is not similar to but specific to the environment. Thus, in the sense of the information-based approach, perception is direct and requires action (Gibson 1979).

Since perception has been regarded as being a relationship between animal and its environment, exploring the “objects of perception” has been essential part of the research relating to perception and action. Then, what are the objects of perception? What is that you perceive when you look at a chair? What are you aware of when you perceive the chair? What is the function of the perception? In the literature perception is considered as it serves two functions: to aid in recognition and to serve as an action-guide. Gibson, however, emphasized that primary function of the perception is “action-guide,” and he introduced the concept of “affordance” to refer to the “objects of perception.” He asserted that looking up nouns and adjectives to express the qualities such as shape or color of the objects (environment) is not the right way to answer the “objects of perception” question (as did Locke 1700):

The psychologists assume that objects are composed of their qualities. But I now suggest that what we perceive when we look at objects are their affordances, not their qualities. . . The differences between [affordances] are not clear-cut, and the arbitrary names by which they are called do not count for perception. If you know what can be done with a graspable detached object, what it can be used for, you can call it whatever you please. . . You do not have to classify and label things in order to perceive what they afford. (Gibson 1979, p. 134.

Gibson coined the notion of “affordances” as the opportunities for the actions, shaped by the layouts and surfaces in the environment, offered to animal. As stated in Gibson’s definition, affordances are action-relevant properties of the environment specified by information that is directly perceptible by an animal. So, for instance, the shape of a standard-size chair affords sitting for an adult human. Although the use of affordances in the planning and performing of

actions requires animal to perceive them, their existence does not depend upon animal's perception – a chair's capability to support an adult human sitting exist whether or not there is someone there to utilize it. Still, affordances are determined in relation to animals' capabilities – the chair has such capacity with respect to an adult human, but not with respect to a child or an elephant (Gibson 1977, 1979/1986).

As pointed out above, existence of affordances is all about how the physical environment is shaped in terms of action possibilities, whereas perceiving affordances is about whether a specific animal is able to actualize relevant actions to those affordances. The environmental property must be relational to an animal's relevant body part in order to actualize affordances, and an animal's perception of the affordance entails such relation (Gibson 1979; Warren 1984). Considering those characteristics of affordances, Gibson emphasized that standard units and scales used in physics are not appropriate to measure the affordances (Gibson 1979). For example, imagine you come upon a hole, which is 60 inches in width and 90 inches in depth on your path while walking on the street. You do not perceive it as 60-inch width and 90-inch depth hole. Instead, you perceive it as wider than your maximum step length or not and deeper than your knee height or not. By perceiving the hole with reference to your own body scales, you simply avoid mathematical calculations in the decision of whether you could jump over or you should walk around it. The information in such a form also serves better in adjusting your step length while jumping over the hole if you decide to do so. Perception of affordances in relation to own body scales requires animal to be aware of his/her own body scales. Animals gain such awareness through proprioception, which is mainly feeded by acquired information from the exploratory actions (Gibson 1979; Warren 1984). You learn about the length of your stride or the size of your foot through proprioceptive information you obtained while walking, jumping, or stretching your legs (Warren 1984). Perception of the environment always involves perception of self, moving in the environment.

When Gibson was talking about the affordances, he had already been admitted a mutual relationship between animal and its environment. An animal is an actor at some degree while perceiving its environment and is a perceiver at some degree while acting in the environment it lives (Gibson 1979). There is no doubt that nobody can think the existence of an animal without an environment it perceives and acts in. Some people, however, may consider that it is true the other way around. Removing the animal from the environment will not change the environment at all; it is still an environment without any single animal that perceives it and acts in it; as an example of their claim, they may state that the environment had already been there millions of years before the first animal (a living creature) developed in it. In response, Gibson stated that it should not be considered as "environment" until the first animal is presented in it; that was just a physical earth, the subject matter of geology but not psychology (Gibson 1979). In psychological approach, especially in the studies of perception and action, the term, "environment," refers to surfaces and layouts and objects that are surrounding an animal who interactively perceive and act in. What the "environment" meant in psychology should not be confused with the physical earth in physics or geology. The physical earth gets the attention in the atomic and cosmic aspects in which it is not available to animal's perception (Gibson 1979). An animal does not perceive the water as two hydrogens and one oxygen; instead it perceives as something to drink, to swim in, and to get drowned in. Therefore, the environment, at least in the sense of psychology, does not exist unless an animal actively lives in it, just like an animal which does not exist without the environment surrounding it. An animal and its environment cannot be isolated from each other; together, they constitute an inseparable animal-environment system.

From Gibson's perspective, the environment is beyond being just a physical earth. It has meanings and values as long as an animal perceives it and acts in it. As being action-relevant properties, which are available into animal perception, affordances carry meanings and values in the

environment. In other words, affordances are functional, and their functions decide the “meanings” and “values.” Gibson (1979) stated, “the perceiving of an affordance is not a process of perceiving a value-free physical object to which meaning is somehow added in a way that no one has been able to agree upon; it is a process of perceiving a value-rich ecological object” (p. 140). A chair, for instance, is functional as it offers sitting, so its meaning or value for us is its being sittable. We do not perceive the chair *per se* but rather its “sittability.” Being aware of the chair’s sittability, in return, guides our sitting behavior. Similarly, the hole, which is 60 inches in width and 90 inches in depth on our path, meant to be an obstacle for us that requires avoiding. So, the hole guides our avoiding behavior, whether we have to walk around it or we can jump over it.

Gibsonian approach implies that, the concept of affordances inherently emphasizes a reciprocal relationship between perception and action. What an animal perceives in the environment is action possibilities, thus affordances. Actualizing affordances requires perception, which guides actions; and the perceptual information that specifies affordances and guides actions is generated by exploratory actions. Hence, perception and action are reciprocally related to each other; cutting off either one will stamp the other one out. They, together, form a continuous perception-action loop. A continuous perception-action loop refers to a close cycle that reflects how an animal action changes its perceptual input on a millisecond timescale. Thus, depending on that, the action planning, required adjustment in action performing, and resulted perceptual information are all updated continuously in time (Neisser 1976). Thinking of a baseball player, how his/her gaze focuses on a flying ball, and how he/she modifies his/her body orientation and position to be able to catch the flying ball may set a good example in order to understand the continuous perception-action loop. Threading a needle might be another example to understand the continuous perception-action loop as it requires intense eye-hand coordination.

The conception of the continuous perception-action loop is developed and evolved from Dewey’s (1896) remarkable critique of the reflex arc concept. Gibsonian approach in perception fulfills the theoretical background when the reflex arc turns into a continuous perception-action loop. The reflex arc is a linear causal linkage between stimuli and motor response, which has its intellectual roots in the sensation-based approach of perception. Dewey states that “[it] is a survival of the metaphysical dualism, first formulated by Plato” (Dewey 1896, p. 365). The reflex arc concept treats the sensory stimulus and motor response as “separate and complete entities in themselves”; one consecutively follows another, but there is no continuity in the reflex arc concept. Dewey argues that “sensory stimulus and motor response shall be viewed, as divisions of labor, functioning factors, within the single concrete whole...in reality they [sensory stimulus and motor response] are always inside a coordination and have their significance purely from the part played in maintaining or reconstituting the coordination” (Dewey 1896, p. 358, p. 360). Thus, the reflex arc idea is deficient in expressing the unity of the activity whereby breaking the integrity and continuity (Dewey 1896). Dewey used a reaching example for his argument: the exact beginning of a reaching action, according to their analysis, is not a sensory stimulus of light, but it is movement of the eye, head, and body muscles, which is a sensory-motor coordination, looking or in other words an act of seeing. Both the sensation and the movement fall within the same act although the sensation is a function of value of the act, whereas the movement is a function of mechanism and control. Then, the act of seeing reciprocally is bound together with the act of reaching within a larger coordination. The act of reaching requires the guide of seeing and, in turn, stimulates the act of seeing for its continuity. What we are having here, according to Dewey (1896), is not a reflex arc, but an organic circuit. Here, the term “organic” is preferred rather than “reflex” because the subordinate members, sensation and movement, of the coordination reinforce and help out

each other to determine each other either directly or indirectly. Sensation and movement cannot be reduced to stimuli and response which are designated as cause and reflex. All in all, rather than a reflex arc, what Dewey's critique suggests is more akin to a continuous cycle, or even a Möbius band (according to Turvey 2004). Besides that, the definition of perception-action loop in Dewey's critique is not predicative, but impredicative (see Turvey's impredicative definition (Turvey 2004, p. 7)). Turvey, together with Shaw, agrees upon Dewey's argument (Shaw and Turvey 1980). Furthermore, Turvey called attention to use of the term "continuous" for the notion of perception-action cycle: "continual seems to be the appropriate adjective for the notion of a perception-action cycle. A *continual* process is one that goes on repeatedly. Applied to perception and action, *continual* means that perception is intermittent and action is intermittent with moments of non-perception and non-action. In contrast, *continuous* means unending and without interruption (Wilson 1993). It seems more appropriate for the perception-action Möbius band" (Turvey 2004, p. 12).

## Conclusion

Animal, which takes place in the core of all studies in psychology, is always present in an environment as an indispensable part of it. A corollary of such animal-environment mutuality is a continuous interaction of animal with its environment. Perception and action is the way of such continuous interaction and communication between animal and its environment. Keeping that in mind, developing a perception-action theory is critical for understanding the complex behaviors of animals in the environment and their functions. It also helps learning and developing animals' capabilities regarding the environment and the beneficial functionalities in the environment. A well-structured perception-action theory is also strong interest of the studies in robotic technology, bionic prosthesis, and artificial intelligence.

As being one of the fundamental and intriguing topics of psychology, the notion of the perception-action is addressed widely but in various ways by different approaches (i.e., embodied view, functional view, ecological view) of psychology. Some approaches consider the action as distinct entity but caused by perception, whereas others claim that perception and action are inseparable and influence each other reciprocally. Even though there is no universal agreement on a single description for a perception-action theory, all approaches agree on that action plays as a critical role as perception and perception and action unify in one way or other. The reason for this could be that the perception-action research has not been developed as a cumulative science in history, as Neumann and Prinz (1990) pointed out. None of the approaches has systematically built its perception-action research upon an earlier one because of the diversity in their goals and methodologies (Fajen 2009; Neumann and Prinz 1990).

In this entry, the perception-action theory is written in the sense of ecological approach as it is in the most favorable light among all approaches.

## Definition

Improvement in the ability to differentiate between similar stimuli following the repeated presentations of such stimuli without reinforcement or feedback.

## Introduction

Human and nonhuman animals learn about stimuli by simply being exposed to them, with the perception of such stimuli changing as a consequence of repeated experience. This type of unsupervised learning is called perceptual learning (PL), and it requires neither reinforcement nor feedback. While PL has been studied within a number of areas in psychology, human PL has, until only relatively recently, been addressed primarily by studies on perception (e.g., Epstein 1967; Fahle et al. 2002; Goldstone 1998). In contrast, in nonhuman animals, this effect has mainly been studied within the field of associative learning (for a review, see, for instance, Hall 2001; Mitchell and Hall 2014). Within this framework, PL is usually defined as an improvement in the ability to differentiate between similar stimuli, an outcome that can be behaviorally assessed in several ways. For nonhuman animals, PL is inferred from the facilitation of performance on a subsequent discrimination task in which one stimulus (e.g., AX) is reinforced and another similar stimulus is not (e.g., BX, where A and B represent the distinctive elements of the stimulus and

X those features shared in common). PL can also be evaluated by a generalization test following pre-exposure to the stimuli and the subsequent conditioning of one of these stimuli. In this case, a PL effect is confirmed if generalization between similar stimuli is reduced after pre-exposure relative to a control condition that received no pre-exposure to the stimuli. In humans, the ability of people to differentiate between similar stimuli after pre-exposure is inferred from the accuracy with which they are able to judge them as same or different or the extent to which they assign similar stimuli to different artificial categories.

PL began as a challenge for the standard associative theory of learning, which traditionally assumed that reinforcement is necessary in order for learning to occur (Spence 1936). One of the earliest theoretical approaches to PL was provided by William James (1890). According to James, discrimination between stimuli improves because, during pre-exposure, associations are formed with other stimuli from the environment. Due to the variability of the stimuli present in a certain situation, each stimulus is associated with different stimuli by chance, with the mental representations of such stimuli becoming increasingly distinct by virtue of their associates. According to this initial account, perception becomes less and less accurate with regard to the sources of stimulation provided by the environment. A subsequent attentional account outlined by Eleanor J. Gibson (1969) adopts exactly the opposite position. According to this theory, during pre-exposure the stimuli are differentiated by the operation of an attentional shift by which attention is selectively and increasingly directed toward the distinctive features of the stimuli (i.e., those that might not be initially perceived, for instance, A and B in our example) at the expense of the common elements. Such common elements are irrelevant for stimulus differentiation, and thus, according to Gibson, the operation of this attentional shift leads to a greater correspondence between perception and the sources of stimulation “because what is learned is not the addition of something but the extraction of something” (Gibson and Levin 1975, p. 23). Moreover, she provided the first experimental reports of both

human and nonhuman PL. In the case of human PL, Gibson and Gibson (1955) presented a target nonsense scribble to children of different ages. Children were then presented a series of similar scribbles and then asked which of these scribbles were exactly the same as the target. They found an improvement in the specificity of the “same” responses with the repetition of the series, an effect that was stronger in older children. According to Gibson and Gibson (1955), the improvement in the ability to differentiate the target from the other scribbles constitutes a PL effect. In the case of nonhuman PL, Gibson and Walk (1956) presented rat pups’ two relatively complex shapes – a circle and a triangle – on the wall of their home cages. The animals and others without experience with the shapes were trained on a discrimination learning task, and it was observed that learning proceeded faster in the former group in comparison to the latter. Unfortunately, Gibson did not offer further details in regard to the operation of the vague attentional shift proposed in her theoretical account. She did, however, specify the pre-exposure conditions under which the attentional shift might occur, that is, the conditions that would be expected to promote stimulus comparison. This hypothesis guided the focus of further research about PL toward the effects of pre-exposure schedules – those that more or less favor stimulus comparison – and, consequently, the more recent associative and nonassociative theoretical models of PL have largely emerged in order to explain such effects.

### Pre-exposure Schedule Effects

The effects of the pre-exposure schedule have been experimentally studied using several procedures and a variety of species (for a review, see Hall 2001; Mitchell and Hall 2014). Currently, most of the evidence in nonhuman animal PL comes from conditioned taste aversion preparations with rats (e.g., Honey et al. 1994; Honey and Hall 1989; Mackintosh et al. 1991; Symonds and Hall 1995). In these preparations, similar stimuli – e.g., similar compounds of flavors, AX and BX – are pre-exposed. One of these

stimuli – e.g., AX – is then paired with toxicosis, and the extent to which the conditioned aversion acquired by AX generalizes to the other stimulus – e.g., BX – is then tested. With human participants, most of the tasks used to assess stimulus differentiation involve same/different judgments of stimuli that are sequentially presented after being pre-exposed or categorization tasks where participants are required to assign similar stimuli to different categories (e.g., Carvalho and Albuquerque 2012; De Zilva and Mitchell 2012; Lavis and Mitchell 2006; Wang et al. 2012; but see also Angulo and Alonso 2012). The so-called *intermixed-blocked effect* has been found in the vast majority of cases using these experimental procedures in both human and nonhuman animals. This effect refers to the greater PL effect observed following intermixed exposure (e.g., AX, BX, AX, BX) in comparison with blocked (e.g., AX, AX, BX, BX) pre-exposures to similar stimuli. Because the intermixed schedule offers better opportunities to compare between stimuli than the blocked schedule, this finding is entirely compatible with the Gibsonian account of PL. However, other more recent accounts could also explain this phenomenon.

McLaren et al. (1989; see also McLaren and Mackintosh 2000), for instance, proposed three associative mechanisms to explain the intermixed-blocked effect as well as the general pre-exposure effect. According to this account, during pre-exposure to similar stimuli (e.g., AX and BX), both the distinctive and common elements undergo latent inhibition (LI). Latent inhibition (e.g., Lubow and Moore 1959) is another well-documented pre-exposure effect that refers to the retardation of conditioning to a stimulus after non-reinforced pre-exposure. During pre-exposure to AX and BX, the common element X (from which generalization is expected to occur) is presented twice as often as the distinctive elements. Therefore, the LI suffered by X is greater than that of the unique elements of the compound, which then is observed as weaker conditioning to X. Given that generalization between AX and BX is expected to occur to the extent that they share features in common (i.e., the X elements), generalization between both stimuli would be reduced following pre-exposure. In fact,

pre-exposure to only the common elements of the stimuli can also reduce the generalization between them (e.g., Bennett et al. 1994).

In addition to this LI mechanism, according to McLaren and colleagues, another associative mechanism known as “unitization” also operates during pre-exposure. This mechanism involves the establishment of bidirectional within-compound associations (e.g., Rescorla and Durlach 1981) during pre-exposure (i.e., between A and X during AX trials as well as between B and X during the BX trials). Such associations would, on the one hand, serve to improve the mental representation of the stimulus, thus enhancing stimulus differentiation. On the other hand, however, these associations might also enhance the generalization between the stimuli. Following pre-exposures to AX and BX and subsequent conditioning to AX, when BX is presented on test, generalization would occur not only through the X elements but also by the X-A-US associative chain (US meaning unconditioned stimulus). This source of mediated generalization would lead to an increase in the generalization between similar stimuli following pre-exposure, i.e., the opposite to what might be expected on the basis of the PL effects just described. However, after intermixed pre-exposures to the stimuli, another mechanism would operate to cancel out this source of mediated generalization. According to McLaren et al. – and in line with the standard associative theory of learning (e.g., Rescorla and Wagner 1972; Wagner 1981) – when the presence of one stimulus element repeatedly retrieves the representation of another absent element, this will lead to the establishment of inhibitory links between them (e.g., Espinet et al. 2004, 2008; Polack and Miller 2019). This should in particular be the case during intermixed pre-exposures to the stimuli (Espinete et al. 1995; see also Artigas et al. 2001; Bennett et al. 1999; Dwyer et al. 2001). After the establishment of these within-compound associations, the X element might associatively activate the mental representation of A on the BX trials, as well as B during AX pre-exposure trials. Therefore, mutually inhibitory links would be established between the distinctive elements of the stimuli – A and B. Thus, although on the test trial the conditioned aversion acquired by AX would still directly generalize to BX on the

basis of the X elements, the mediated generalization source would be canceled because the element B will now inhibit the associative activation of A, breaking the X-A-US chain. During blocked pre-exposures to the stimuli, on the other hand, the establishment of inhibitory links between the distinctive elements of the stimuli would be hindered. On the first block of pre-exposure trials – e.g., with AX – the within-compound B-X associations would not be established, and B cannot be associatively activated. Moreover, during the second block of trials with BX, the within-compound A-X association would gradually be extinguished. Thus, the associative activation of the distinctive elements of the stimuli – as well the subsequent establishment of inhibitory links between them – would be prevented. As a result, the mediated generalization source would operate during the test with BX, with generalization then being stronger in comparison with that observed following intermixed pre-exposure.

The *intermixed-blocked effect* has also been explained from other theoretical approaches that predict changes in the salience or perceptual effectiveness of the stimulus as a consequence of pre-exposure. For instance, Hall (2003) proposed a salience modulation mechanism by which the salience of the distinctive elements of the stimuli increases following intermixed exposure in comparison with blocked pre-exposure. According to this account, during pre-exposure all the elements of the stimuli lose salience due to a process of habituation (e.g., Hall 1991). Given that during pre-exposure to AX and BX the common elements X are pre-exposed twice as often as A and B, the latter elements would maintain more salience than the former, thereby enhancing stimulus differentiation in general after repeated pre-exposure. In addition, Hall (2003) hypothesized that salience might be restored if the stimuli are associatively activated. As outlined previously, the associative activation of the mental representation of the distinctive elements of the stimuli would be facilitated during intermixed pre-exposures relative to blocked exposures. Therefore, the salience of such elements would be expected to be higher after intermixed than blocked pre-exposures (e.g., Blair et al. 2004; Blair and Hall 2003). In animal conditioning

procedures, the greater generalization decrement observed after intermixed than blocked pre-exposures would come from two sources. First, the more salient A element would be more effective in overshadowing X on the AX conditioning trials, and therefore the aversion acquired by the X element (and thus subsequent generalization to BX) would be weaker after intermixed pre-exposure. Second, B would also be more effective at interfering with the aversion to X on the test with BX.

Focusing on the effects of the temporal interval between the stimulus presentations, Mitchell et al. (2008) invoked memory mechanisms to explain why the distinctive elements of the stimuli might be better coded in memory – and thus more effective for stimulus differentiation – after intermixed than blocked pre-exposure. According to the memory theories of the massed-spaced effect (e.g., Ebbinghaus 1885/1964, see also Glenberg 1979; Jacoby 1978; Wickelgren 1972), spaced practice produces better memory of the stimuli than massed practice. During intermixed pre-exposures to AX and BX, the distinctive elements of the stimuli are presented on alternate trials, while during blocked pre-exposures such elements are presented on consecutive trials. The practice with the distinctive elements would then be more spaced in the former than in the latter case, with the result being that the elements would be better encoded in memory and available for stimulus differentiation (e.g., Lavis et al. 2011; De Zilva and Mitchell 2012).

Such theoretical accounts have been tested in various studies, and in general, all seem to generate evidence both for and against their predictions, with all of them being equally able to explain the *intermixed-blocked effect*. Most of these accounts, however, have failed to explain the effect of the another pre-exposure schedule, at least in terms of the same mechanisms proposed to explain the intermixed-blocked effect. This pre-exposure schedule is the controversial *concurrent pre-exposure schedule*. Simultaneous or concurrent pre-exposures to the stimuli might be expected to offer the best opportunities to compare them because they are presented as close in time as possible. The Gibsonian account would predict better stimulus differentiation after

concurrent than blocked pre-exposures to the stimuli, while none of the other theoretical accounts could explain this finding. During concurrent pre-exposure to the stimuli, the distinctive elements of both stimuli would be physically present; therefore, no inhibitory links would be established between them, nor would their salience be restored. Moreover, the temporal interval between their presentations would be the shortest possible, nominally nonexistent. Several studies have addressed this issue and have found different results for human and nonhuman animals. In humans, in particular, concurrent pre-exposure appears to enhance stimulus differentiation to a greater extent than the intermixed or blocked schedules (e.g., Angulo and Alonso 2012; Mundy et al. 2007, 2009). Moreover, evidence for an attentional shift of the sort described by Gibson (1969) has also been found using eye-tracking methodologies, where dwell time for gaze fixations is assumed to represent attentional focus (Angulo et al. 2019). However, most of the studies conducted with animal subjects have found greater generalization between stimuli following simultaneous than with intermixed pre-exposure (e.g., Alonso and Hall 1999; Rodríguez and Alonso 2004; Rodríguez et al. 2008; see, however, Angulo 2018, for different findings). Rapid alternation between the stimuli also appears to increase generalization (e.g., Bennett and Mackintosh 1999; Honey and Bateson 1996). Thus, if the same logic applied to previous findings is applied here, these results would suggest poorer stimulus differentiation following concurrent than intermixed pre-exposures in non-human animals. Because the theoretical accounts of PL make different predictions regarding the effects of a concurrent pre-exposure schedule, this issue has, in recent years, been the focus of much interest for researchers within the field.

### Current Challenges for Perceptual Learning

Verbal instructions are an issue that has attracted increasing attention regarding the effects of the concurrent schedule in humans and nonhumans.

In the majority of these studies, participants were instructed to more or less explicitly search for the differences between the stimuli during pre-exposure (e.g., Angulo and Alonso 2012, 2013; Mundy et al. 2007, 2009). Instructions can be expected to induce processing of the stimuli in a rather different way compared to experiments conducted with animals. For instance, while in humans the stimuli are processed in a top-down manner, other animals process the stimuli in a bottom-up way (Tsushima and Watanabe 2009). This possibility has also been discussed regarding whether instructions could promote a self-supervised form of learning in humans, as opposed to the unsupervised form of learning that is assumed to occur in other animals (Watanabe et al. 2001). Finally, it has also been proposed that an attentional response – in this case focused on the distinctive elements of the stimuli – might be instrumentally conditioned when the instructions ask for stimulus differences, since finding such differences could be a source of reinforcement (Mackintosh 2009).

The findings of some studies seem to confirm an important effect of instructions directing participants toward stimulus differences, both in terms of stimulus differentiation and attentional shift (e.g., Angulo et al. 2019; Navarro et al. 2016). For instance, participants appeared to be more accurate at making same/different judgments after concurrent pre-exposures when they were required to judge the stimuli as same or different, or only as different, compared to participants instructed to judge the stimuli as same or to simply look at the stimuli. Moreover, the instructions asking for same/different or only different judgments also increased the attentional shift toward the distinctive elements of the stimuli compared to nonspecific instructions to only look at the stimuli (Angulo et al. 2019). This pre-exposure condition is more similar to that of animals, and, even in this case, some evidence for an attentional shift was found during concurrent but not during blocked pre-exposures to the stimuli. In light of these findings, instructions directing the participants toward stimulus differences might increase PL as well as an attentional shift akin to that

described by Gibson. Such effects might also arise during concurrent pre-exposure without instructions guiding attention to the distinctive elements of the stimuli. Thus, it is unlikely that differences in the effect of the concurrent pre-exposure schedule in humans and nonhuman subjects animals depend on the instructions, at least exclusively.

Other studies have focused on conditioning procedures using nonhuman animals. As stated before, in this case the ability to discriminate between the target stimuli is inferred from the level of generalization, and the concurrent schedule might increase the generalization between stimuli in at least two ways. First, according to the standard associative theory, when the stimuli are concurrently presented, one would be associated with the other, thereby increasing the generalization between them. Second, stronger conditioning to the common elements of the stimuli has been found following concurrent pre-exposure, these being the elements through which direct generalization occurs (e.g., Rodríguez and Alonso 2008; Rodríguez et al. 2008). To date, it is not clear as to whether or not these factors might operate regardless of the ability of animals to differentiate between the stimuli (for a discussion, see, for instance, Mitchell 2009). But a recent series of experiments seems to indicate that, at least in a situation in which it is assumed that the animals discriminate between stimuli, concurrent pre-exposure does not enhance generalization relative to intermixed pre-exposure (Angulo 2018).

Current discrepancies between the findings of human and nonhuman PL studies remain to be clarified. In this regard, some authors have suggested that PL mechanisms might differ between human and nonhuman animals. However, before accepting this possibility, research should first rule out the possibility that these differences might arise from the procedural differences between the experimental preparations used in humans and nonhumans. This might be an important future line of research, in order to achieve a unified theory of PL able to explain the generality of pre-exposure effects. In this regard, a thorough analysis of the procedures

used to present the stimuli might help reach this objective.

Mesocortex; Proisocortex

### Definition

Perirhinal cortex is the cortical gray matter found in or around the vicinity of the rhinal sulcus and is of intermediate type between the archicortex and neocortex.

### Introduction

The perirhinal cortex (PC) is a proisocortical area that interconnects the hippocampal formation with other parts of the limbic lobe and with the lateral temporal and occipito-temporal association cortices. It is closely interconnected with divergent unimodal and polymodal association area of the neocortex as well as with the hippocampal formation and the amygdala (Suzuki 1996).

PC is present only in mammals and marsupials and has undergone evolutionary changes. It is just a narrow strip of the cortex in non-human primates, while it is of significant size reaching a length of about 3 cm and a calculated area of about 8cm<sup>2</sup> in humans (Insausti et al. 1998).

### Location

As the name indicates, the perirhinal cortex is found in or around the vicinity of the rhinal sulcus. The PC is located on the ventral surface of the brain in the medial temporal lobe, lateral to the rhinal sulcus running rostrally and dorsally up to the temporal pole from its caudal border. The medial relation of PC is formed by the piriform and periamygdaloid cortices rostrally and by the entorhinal cortex caudally (Suzuki et al. 1993).

### Structure

The perirhinal cortex is composed of two Brodmann areas: area 36 (larger, laterally situated, and dysgranular) and area 35 (smaller, medially situated, and agranular) (Insausti et al. 1998). Area 36 is divided into three subdivisions: 36d, 36r, and 36c. 36d is the most rostral and dorsal and 36c is the caudal extreme of the PC. Between them is 36r. Area 35 can be divided into two divisions: 35d and 35v (dorsal and ventral, respectively) (Suzuki and Amaral 1994).

### Histology

PC does not have a clear columnar organization. It is proisocortex in architecture. Area 36 is characterized with uniformly distributed small neurons in layer II, medium pyramids in layer III, ill-defined thin layer IV, and not differentiated large pyramids in layers V–VI. Area 35 is characterized with accentuated layer II having a mixture of small and slightly larger dark neurons, thin layer III having lack of cellular density, and absent layer IV and contains not well-differentiated very large neurons in layers V and VI (Insausti et al. 1995).

### Connections and Functional Significance

The perirhinal cortex is highly interconnected with many other brain regions including the amygdala, basal ganglia, frontal cortex, etc. and acquires highly refined sensory information of all

modalities from all sensory areas. It forms a crucial gateway for bidirectional transfer of information through the hippocampus and limbic system. When a stimulus may be recognized, the PC processes its association with past history. Thus, it plays an important role in sensory perception and memory associations. In monkeys, the PC receives sensory information predominantly from high-level visual areas, while in rodents, it receives predominantly from olfactory and, to a lesser extent, auditory areas (Meunier et al. 1993).

PC outputs include the following:

1. Medio-dorsal nucleus of the thalamus via the ventral amygdalofugal pathway
2. Anterior thalamic nuclei and mammillary bodies via the fornix
3. Other cortical regions known to be involved in visual recognition memory, such as the ventromedial prefrontal cortex via pathways such as the uncinate fasciculus

Because of these connections, PC is involved in learning and memory (Biagini et al. 2013), visual recognition memory in monkeys (Meunier et al. 1993), object recognition memory in humans (Squire et al. 2007), item-based memory (coding familiarity/recency of items, Gold et al. 2006), and item-context-based memory associations when the stimuli are objects (Graham et al. 2010) and is essential for incidentally learning the order of events in episodic memory (Allen et al. 2020). According to Barbeau et al. (2004), the PC seems to support context-free (non-episodic) knowledge and “item-specific” memories.

## Clinical Disorders

Damage to PC disrupts stimulus-stimulus associations and object recognition abilities finally leading to impairment of visual recognition memory. Any pathological involvement of the monkey PC may impair their ability to identify familiar objects presented in new views (Buckley and Gaffan 1998). Human studies show that any pathological lesions in PC leads

to impairment in discriminating among object concepts having a high degree of visual semantic overlap among choices, such as between a hairdryer and a gun (Douglas et al. 2019). PC may also be implicated in the pathological processes of epileptogenesis and ictogenesis such as the kindling phenomenon and the spread of limbic seizures (Biagini et al. 2013). Recent studies show that PC appears to play an essential role in gustatory neophobia and its attenuation in rats (Ramos 2020).

## Conclusion

The perirhinal cortex has a distinct modular organization in human brains and is strategically located in the medial temporal lobe to influence the flow of information into and out of the hippocampal formation. This region appears to be affected in various diseases like Alzheimer’s, causing alterations in memory. Despite lot of studies on the structural and functional aspects of PC, still there are many unfolded secrets in this small structure that needs to be studied in the future.

## Introduction

Perissodactyla comprise the tapirs (Tapiridae), the rhinos (Rhinocerotidae), and the equids (Equidae). In order to evaluate their cognitive capacities, it is important to consider the species' social and environmental challenges (Griffin et al. 2017). Only by knowing the challenges, to which animals have to adapt, their cognitive capacities can be relativized to other species, for example, if humans are not encountered on regular basis, animals may not need to learn how to read human given cues, even though they may be able to do so in a captive situation.

The Perissodactyla show large variation in their social organization, and in the environments in which they live. All Perissodactyla species are heavily hunted and some species, such as the Asian Baird's tapir (*T. bairdii*), the Malayan tapir (*T. indicus*), the Indian rhino (*Dicerorhinus sumatrensis*), and the Javan rhino (*Rhinoceros sondaicus*) have become nearly extinct as a result. The Przewalski horse was extinct in the wild but was successfully reintroduced into the

Mongolian and Kazak steppe. Some species are exclusively wild while others species have domesticated groups, which are considered to be the same species. All Perissodactyla have to adjust to human-dominated environments (Grzimek et al. 2003).

Below, the particular Perissodactylas' social systems and environments will be briefly described. Thereafter, the state of the art in cognition research will be presented for each species. Cognition research is scarce in the exclusively wild species of tapirs, rhinos, zebras, and horses. This is mostly due to the fact that the species are difficult to observe, because they live in remote areas and because only a few animals are left in the species which are close to extinction.

### The Tapirs (Tapiridae)

#### Habitat and Social Organization

Four extant tapir species are described, the central American lowland tapir (*Tapirus terrestris*) and the mountain tapir (*T. pinchaque*), as well as the Asian Baird's tapir (*T. bairdii*), and the Malayan tapir (*T. indicus*). All species live solitary, avoid contact with humans, live in remote areas of rain forests or mountains, and are facultative nocturnal in areas with high hunting pressures through humans (Grzimek et al. 2003).

#### Social Cognition

Lowland tapirs and Malayan tapirs recognize the voices of their own species (Zenzinger 2010). It was suggested, that they are capable of identifying individual tapirs, i.e., show cognitive capacities of individual recognition, as they live in overlapping territories, mark their territories with urine, and show flehmen behavior when investigating scent marks (Pinho et al. 2014). When animals "flehmen," they lift the upper lip and lay open the efferent duct of the vomero nasal organ, an organ which is used for the investigation of highly volatile odors or even pheromones of, for example, individual animals. Marking behavior and scent mark investigations would be useless if the animal could not infer the donors' species, sex and, maybe the individual identity, from the marks.

### The Rhinos (Rhinocerotidae)

#### Habitat and Social Organization

Rhinos comprise five extant species. All five species are heavily hunted, mostly because their horn is given credit for enhancing human virility, a misconception. The three Asian species, the Asian rhinoceros (*Rhinoceros unicornis*), the Indian rhino (*Dicerorhinus sumatrensis*), and the Javan rhino (*Rhinoceros sondaicus*) live in remote rain forest habitats. The black rhinoceros (*Diceros bicornis*) and the white rhinoceros (*Ceratotherium simum*) inhabit the African savanna. Little is known about the behavior and cognition in the two nearly extinct species, the Indian rhino and the Javan rhino. They avoid contact with humans and live solitary (Grzimek et al. 2003).

Asian rhinoceroses are facultative solitary. Sometimes they form small female groups with offspring, which are hierarchically structured in so-called matriline. In matriline, offspring is usually dominated by their mothers and mothers by the grandmothers. Very seldom, females of the Asian rhino are accompanied by bulls and, seldom, bulls gather in small bachelor groups. Both, females and males mark their home ranges, which can overlap, with feces and urine (Grzimek et al. 2003).

Black rhinoceroses are mostly solitary but have also been described to live in small groups of some females with offspring and sometimes, with a bull close by. Bulls are rarely seen together. They are not strictly territorial, i.e., they do not strictly stay in defined home ranges, but males and females show marking behavior with dung and urine. Feces piles may reach the height of half a meter (Grzimek et al. 2003).

White rhinoceroses are the most social rhinos. However, they appear to need retreat areas for withdrawing from conspecifics, as black and white rhinoceroses, suffer from social stress when several pairs are kept in small zoo enclosures (Carlstead and Brown 2005). In past decades, white rhinos were said to form social networks within their groups of up to eight females and their offspring (Grzimek et al. 2003). Today, animal numbers are reduced through human hunting and group sizes reach

only three females. White rhinos are territorial, i.e., they stay in defined home ranges, and, especially the solitary bulls that mark their overlapping territories with feces and urine.

### Social Cognition

Because marking behavior and intense scent mark investigation are shown frequently in black and white rhinos (Grzimek et al. 2003), it is not surprising that their abilities in social and individual recognition are highly developed. The animals appear to have a strong need to identify group members, mating partners, or rivals in their territory. Black rhinos use olfaction to identify the age, the sex, and the individual identity of conspecifics. White rhinos can identify familiarity and the sex, age, territory, and estrous state of fecal donors (Marneweck et al. 2017). Furthermore, white rhinos discriminate the species and the sex of other rhinos from contact calls (Cinková and Policht 2016; Fig. 1).

### Object Discrimination

Because vision is poorly developed in rhinos, it was said that rhinos have troubles to differentiate between an inanimate person and a tree from a distance. Thus, fast exploratory approaches to humans may have been mistaken for attacks, and some rhinos were shot by mistake (Grzimek et al. 2003). However, vision may not be as poor as expected, because black and

white rhinos are able to learn visual object discriminations. They discriminated black symbols, a triangle and a circle, on white cards (Daniel and Mikulka 1998).

### The Equids (Equidae)

Equids comprise zebras, donkeys, and horses. They can be crossbred and sometimes wild animals crossbreed in overlapping habitats. Equid hybrids are generally called zebroids. They are termed mules when donkeys breed with horses, zebrules, or zedonks when donkeys breed with zebras, and zorse when horses and donkeys breed. The hybrids are usually infertile.

### Zebras

#### Habitat and Social Organization

Zebras comprise three, exclusively wild species, Plains zebra (*Equus burchelli*), Cape mountain zebra (*E. zebra zebra*), and Grevy's zebras (*E. grevyi*). Zebra species can be assigned to type I and type II social systems (Klingel 1972; Fig. 2). Plains zebras and Cape mountain zebras live in the African Savanna and form type I social systems. They live in harem groups with several females, their offspring, and one to three mature males. Surplus males gather in bachelor groups. Several of these subgroups may form herds of 200 to 1000 animals (Klingel 1972). Mostly linear hierarchies are formed within and between

### Perissodactyla

#### Cognition, Fig. 1

Contact calls in white rhinos. (a) Depicts the pant call of an adult female and (b) of an adult male. The calls waveform is given above and the spectrogram below of it, time on the X-axis and frequency (kHz) on the y-axis. The Spectrogram parameters are: FFT length 1024, frame size 100% and overlap 87.5%. I = the inhalation and E = the exhalation of the animals (Cinková and Policht 2016)

**Perissodactyla Cognition, Fig. 2** Equid social systems. In type I social organizations, depicted above, females (♀), offspring (juv), and males (♂) live in mostly stable groups with usually one alpha male and several females with their offspring. Whereas, in type II organizations, depicted below, several males protect particular habitats and

dominate loosely bonded females and males that travel through these areas (Klingel 1972). In recent publications *Equus Quagga* is termed *Equus burchellii*, *Equus zebra* is *Equus zebra zebra*, and *Equus africanus* is referred to as *Equus asinus*

subgroups and animals are bonded with group members, they form so-called social bonds. The linearity of the hierarchies and the numbers of social bonds between group members differ between groups (Fischhoff et al. 2007).

Grevy's zebras live in remote African mountains with little vegetation and water. They form type II social systems (Fig. 2). Solitary males defend a territory around a water source and mark the borders with feces. The males claim mating rights over the females within their territory. Whether females form social groups depends on the resource availability. When food and water is scarce, females live solitary with their offspring. In periods with plenty of food and water, they form small groups.

#### Social Cognition

Plains zebras protect their social bonds through intervening in interactions of others (i.e., third party intervention). Foals, yearlings, and adult mares intervene, when bonded group members exchange friendly behaviors (affiliative interventions), yearlings and foals intervene when their mothers are attacked by stallions, and stallions, in multimale groups (agonistic interventions), intervene into courtship behavior (sexual

interventions), especially when bonded females are involved (Schilder 1990).

When Grevy's zebra females have to walk long distances to water sources, they were described to leave their sleeping offspring behind. One or two mature animals stay with the "kinder garden" (Klingel 1972). The report indicates abilities in social and individual recognition in Grevy zebras. Further cognitive abilities were not reported.

#### Spatial Cognition and Movement Decisions

Abilities in spatial cognition allow plains zebras to find distinct paths for short and long distance movements (Brooks and Harris 2008), while the exact mechanism is not known. They use spatial memory for orientating on landmarks, but orientation on the magnetic field may also play a role.

Plains zebra group movements appear to arise out of a mix of low cognitively demanding self-organized movements, in which group members synchronize their movements with group members mostly without making any decisions, and out of decisions on whom to follow. For example, lactating females initiate movements towards water more often, because of their enhanced need for water, but how many group

members will follow depends on the quality and the quantity of their social bonds within their group, i.e., on the number of group members deciding to follow this specific animal (Fischhoff et al. 2007).

## The Donkeys

### Habitat and Social Organization

Donkeys comprise the African wild ass (*Equus asinus*), Asian wild ass (*E. hemionus*), the Kiang (*E. kiang*), and domesticated types. All form type II social organizations (see Fig. 2). Some individuals in donkeys and wild ass appear to mark their territory with urine and feces (Klingel 1972). The wild ass is close to extinction. They avoid contact with humans, and roam in steppe or semidesert habitats, in very remote areas where they can escape heavy hunting. The herds comprised more than 1000 individuals in the past, which went down to few extant herds with less than 200 individuals in recent years.

### Social Cognition

Research on cognition in wild ass is missing but some work has been conducted in domestic donkeys. Anecdotal reports on strong pair bond formation between domestic donkeys were scientifically confirmed. Donkeys identify bonded individuals and prefer to stay close to them (Murray et al. 2013).

### Spatial Cognition

Domestic donkeys appear to have a good short-term memory of between 10 s and 30 s for locations where food disappeared through a barrier (Baragli and Regolin 2008). In a comparative approach, mules (hybrids between donkeys and horses) were superior to donkeys and horses, to learn a path around a barrier. When the gap in the barrier was moved from location A to location B, horses kept returning to the old, now closed gap (A), while mules and donkeys approached the old and the new gap (A and B) on equal terms (Osthaus et al. 2013). Mules and donkeys, therefore, show a higher plasticity in reasoning about

spatial conditions, i.e., in spatial cognition, than horses.

### Object Discrimination

When donkeys, mules, and horses were compared for how many pairs of particular patterns on paper cards they would learn to discriminate within 25 sessions, five out of six mules, but only one horse out of six and no donkey out of six discriminated three different patterns (Proops et al. 2009). The superiority of mules in discrimination learning was discussed to be a matter of hybrid vigor. However, it remains a matter of debate whether the horses gradual and the donkeys' fast decline in performance is rather due to an attention loss than to discrimination learning capacities.

## The Horses

### Habitat and Social Organization

Horses include the domestic horses (*Equus caballus*), the feralized domestic horse (*E. ferus caballus*), and the wild horse (*E. ferus przewalskii*). They prefer steppe habitats but adapt easily to different habitat types. All the horses form type I social organizations (Fig. 2). In contrast to the teaching of some traditional textbooks, harem, and group stability varies considerably between groups of horses (Rubenstein 1986). All-male "bachelor" bands are unstable in feral horse populations with only a few exceptions (see for review: Linklater 2000). While some large harem horse groups show stable smaller core groups, between 90% and 100% of the male offspring and between 80% and 90% of the female offspring disperse from their natal harem groups when they reach maturity. They either join an existing harem or bachelor group or form new groups by themselves. Adult mares sometimes disperse from harems and return.

### Social Cognition

All species build social bonds with up to three animals, form alliances between females for offspring protection, and protect social bonds

through third party intervention similar to plains zebras (see above; Krueger et al. 2015). Horses even show postconflict resolution, by consoling group members, which were object to aggressions from others.

The horses' social system resembles a fission-fusion society, in which animals need to identify the departing and returning group members. In this partially unstable system, horses can stay in contact through distance calls. They identify group members by their whinnies, by their visual appearance, and at the smell of their fecal marks (Krueger and Flauger 2011).

### Horse-Human Recognition and Interaction

The domestication of horses 3000–6000 years ago may have shaped interspecies communication abilities. The skill of horses in responding to human facial and gestural cues is known from the case of Clever Hans in the early twentieth century. Clever Hans was claimed to have the arithmetic skills of a 12-year-old child. Clever Hans presented the solutions for the mathematical tasks by tapping the desired number with his hoof. Although subsequent observations revealed that he could not count, he was, nevertheless, extremely skillful in reading subtle human facial expressions and body movements, which he used for his decision when to begin tapping with his hoof and when to stop. Clever Hans even generalized the cues given by his trainer to unfamiliar persons (Pfungst 1907).

The discovery of Clever Hanses "shortcut" to solving mathematical equations stigmatized cognition research in domestic animals and even more in horses for about 100 years. Nobody dared to approach evaluating whether Clever Hanses skills in reading human given cues were unique or common in horses. Only in the last decade, some research was conducted in this area. Today, we know that horses identify humans individually. Domestic horses are able to use human hand pointing gestures and human head and body orientation to find food. Domestic horses orientate in the direction of human

attention, for example, when humans turn away and stare in particular directions. Domestic horses distinguish between familiar and unfamiliar persons, generalize positive and negative experiences with humans from one human to others and infer emotional states of humans from human photos. Some horses have negative or positive expectations of human behavior, which they acquired in earlier encounters with humans. They may refuse to participate in a test when they expect humans to solve the task for them or when they wait for distinct signals for what they are expected to do (for horse-human interaction see: Hausberger et al. 2008; Schuetz et al. 2016).

### Spatial Cognition and Object Permanence

Interestingly, the horses' short-term spatial memory was said to decline after 10–30 s. Still, in a detour task feral ponies, raised in a semiwild environment, showed an understanding of object permanence, i.e., of the fact that an object which is no longer perceivable still can be regained, even after a delay of 10 s. Nevertheless, Standardbreds which were raised in traditional stabling did not succeed in the task (Baragli and Regolin 2008). Limitations in some horses' spatial reasoning may hamper their performances in simple detour tasks (Baragli and Regolin 2008; Osthaus et al. 2013). However, studies on whether the length of domestication, the aim of the domestication, the management of the horses, or the environment affect the learning capacities or the performance of domestic horses in cognition tests are needed.

### Movement Decisions

As horses have a strong urge to stay with group members for protecting offspring and for fleeing together decisions on moving the group need to be made. Group movements can be initiated by the despotic herding of alpha males. In Przewalski horses and feral horses, however, any group member may initiate movements by departure (Kruger et al. 2014b). Movement initiations by departure are not exclusive to any type of individual, as has been claimed for so-called

**Perissodactyla Cognition, Fig. 3** Horses try to recruit humans by referential communication. Horses (a) gaze to the experimenter or (b) point at a bucket with food for

communicating their interest in the bucket (Malavasi and Huber 2016)

lead mares. Instead horses show a limited form of distributed leadership, with higher ranking animals being followed more often. Most horse movements appear to be self-organized, with little need for cognitive decision-making. However, the fact that social rank affects whether animals are followed or not implies that decision-making on the reliability of the initiating animal takes place. So far, recruitment of group members could not be proven.

However, horses showed distinct recruitment behavior towards humans, when they tried to point humans to opening a gate for getting access to food (Malavasi and Huber 2016; Fig. 3). They even increased their effort when the person in reach was inattentive (Ringhofer and Yamamoto 2017).

### Object Discrimination, Categorization, and Generalization

In individual learning tests, horses discriminate precisely between objects. They learn object categories and concepts and even generalize them to unknown objects (Hanggi 2003; Hanggi and Ingersoll 2009; Fig. 4). For object categories and concepts some horses show an impressive long-term memory of 7 years and 10 years (Hanggi and Ingersoll 2009).

Only lately it was experimentally shown that Shetland Ponies have a number concept which allows them to discriminate between numbers of up to five depicted objects on computer images (Gabor and Gerken 2014).

**Perissodactyla Cognition, Fig. 4** Horses discriminate pictures. Horses were able to understand (a) categories (filled versus open-center stimuli) and (b) concepts (small versus large stimuli; Hanggi 2003; Hanggi and Ingersoll 2009)

### Social Learning

Finally, the Social intelligence hypothesis claims that animals which live in complex social systems face higher cognitive demands. They need to

**Perissodactyla Cognition, Fig. 5** Social learning in horses. (a) Shows the situation in which a demonstrator horse (dem) opens a feeding apparatus by pulling a rope. An observer horse (obs) watches the demonstration. (b)

Shows a successful observer when operating the feeding apparatus. (c) Depicts the feeding apparatus in detail. A rope (1) had to be pulled to open a drawer (2) (Krueger et al. 2014)

identify group members and deal with conflict. Further above, we showed that horses are capable of both. For decades, researchers had difficulties to prove social learning in horses. By now, we know that horses learn from observing other horses (Krueger et al. 2014a) and from observing humans (Schuetz et al. 2016; Fig. 5).

Horses copy the social behavior of other horses, adapt to the expectations of other horses when crossing a carpet, and learn to open a feeding apparatus by observing other horses (Fig. 5) or familiar persons. Interestingly, horses learn from higher ranking, older horses in their social group (Krueger et al. 2014a). Apart from individual trial and error learning, stimulus and local enhancement has been discussed to be the primary social learning mechanism in horses (Krueger et al. 2014a; Schuetz et al. 2016).

## Conclusion

Cognition research has been conducted in the particular Perissodactyla species to quite different amounts. This appears largely to be due to the species visibility and to the importance of the

species to humans. For example, in domestic horses, the interest of the public and the amount of cognition research is huge compared to other Perissodactyla species. Some wild Perissodactyla species are even mostly unknown to the public. Unfortunately, some of these species are close to extinction. If we do not hurry up and bring information on their behavior and cognitive capacities into the open, we may miss the chance of getting to know anything about the species' cognition at all.

## Perissodactyla Communication

Katherine Albro Houpt  
Cornell University, Ithaca, NY, USA

### Horses

#### Vocalizations

##### Neigh

The neigh (or whinny) is a greeting or separation call that appears to be important in maintaining herd cohesion. It is most often heard when adult horses or a mare and foal are separated. Stallion neighs contain lower frequencies

than those of mares or geldings. Horses appear able to discriminate between familiar and unfamiliar horses on the basis of their neighs alone (Lemasson et al. 2009).

A separated mare and foal will neigh repeatedly. These neighs appear to be nonspecific distress calls, which the mare, but not the foal, may recognize individually (Houpt 2017). The neighs of a mare separated from her foal can be distinguished from those anticipating feeding by analysis of their spectral frequencies (Pond et al. 2010).

##### Nicker

The nicker, a low volume call, is a care-giving (epimeletic) or care-soliciting (et-epimeletic) call. It is given by a mare to her foal upon reunion and probably is recognized specifically by each. A horse may also nicker to its caretaker and a stallion to a mare in estrus.

##### Snorts, Squeals, and Roars

Nickers or neighs usually elicit a reply; other equine vocalizations, such as snorts, squeals, and roars, do not. The roar is a high-amplitude vocalization of a stallion and is usually directed to a mare. A sharp snort is an alarm call. More prolonged snorting or sneezing snorts appear to be a frustration call given when horses are restrained from galloping or forced to work. Snorts and nickers are sounds from the nostrils. The mouth is closed. Other calls are given with the mouth open.

When two strange horses meet, or when horses have been separated for some time, they greet each other by putting their muzzles together nostril to nostril. The nostrils are flared, but if any vocal signals are given, they are inaudible to humans. Usually one, the other, or occasionally both of the horses will squeal and strike or jump back, although neither has been bitten or threatened. The squeal is, therefore, a defensive greeting. It is heard frequently when horses are forming a dominance hierarchy and many bites are being exchanged. Mares that are not in estrus squeal and strike when a stallion approaches too closely.

A squeal may also be a response to the sudden onset of pain.

### Postures

The horse's ears are probably the best indicator of its emotions. Ears pointed back indicate aggression, and the flatter the ears are against the head, the more aggressive the horse. The submissive horse holds its ears to the side (Dalla Costa et al. 2014). Horses tend to position their ears in the same direction in which they are looking. Thus, when the horse's ears are pointed straight ahead, it is looking straight ahead. Horses are aware of the other horses' facial expressions so that they will approach a feed bucket toward which a photographic image of a horse is looking or pointing its ears (Walther and McComb 2014).

The posture and bodily actions of the horse are also useful in interpreting its moods. The relaxed horse stands quietly, whereas its nervous counterpart prances and chafes at the least restraint. The aggressive horse, when it is threatening to kick, lashes its tail and may even lift one of its hind legs. The frightened horse tucks its tail tightly against its rump and stands with its feet close together. Muscle guarding is seen, especially if the animal anticipates pain. A few mares will urinate and lash their tails, splattering urine, as they are being chased, and it should not be confused with the frequent urination, but with deviated tail, seen in estrous mares. The stallion moving his mares assumes a unique posture, called herding, driving, or snaking, with head down, nearly touching the ground, and ears flattened.

Horses paw the ground, not in aggression, but rather in frustration when they are eager to gallop or, more commonly, when they want to graze and are restrained by rope or reins. Pawing to eat may be a behavior derived from pawing through snow for grass and might be considered a form of displacement behavior. Tail lashing and pawing can be signs of discomfort (Haupt 2017).

A very detailed description of equine facial expression has been made (Walther et al. 2015). Other facial expressions of the horse are more subtle; nevertheless, they can be used profitably to understand a horse's mood. A submissive horse

turns its ears outward. Young horses (less than 3 years old) have a more dramatic display, snapping, also called champing or tooth-clapping, in which the lips are retracted, exposing the teeth that are sometimes clicked together. This expression is shown by a colt to an approaching stallion or toward an adult who is threatening him. The sexually receptive mare shows a unique expression, the mating face, in which her ears are swiveled back and her lips hang loose. She may also exhibit snapping. A horse that sees but cannot reach food, or is anticipating food, makes chewing movements and sticks out its tongue. This may be a submissive signal indicating that the horse is ambivalent-reluctant but motivated to approach.

The pain grimace in horses is characterized by ears laid stiffly back, orbital tightening, tension above the eye area, prominent strained jaw muscles, mouth strained and pronounced chin, strained nostrils, and flattening of the profile (Dalla Costa et al. 2014).

### Tactile Sense

Horses can detect a fly on their skin and respond either by moving their skin or swishing their tails. Riders make use of the horse's ability to perceive a slight pressure on his flank in order to signal dressage movements.

### Olfactory Signals

#### Scent Marking

Olfactory communication plays an important part in the sexual behavior of horses. Stallions curl their upper lip in the Flehmen position or "lip curl" when they smell the urine of a mare. Estrous urine alone does not stimulate more episodes of Flehmen by stallions than does nonestrous urine, but the frequency of Flehmen by a stallion toward a particular mare in his herd increases as she approaches estrus, perhaps because the mare urinates more frequently (Haupt 2017). After the stallion investigates urine by putting his lips in it, his lips are raised in the Flehmen position, the nostril opening is partially blocked and the horse, by breathing deeply, aspirates the urine into the vomeronasal organ. Although stallions

**Perissodactyla Communication, Fig. 1** Flehmen and urine marking by a stallion

Flehmen most frequently, geldings and mares also exhibit the behavior in response to olfactory or gustatory stimuli. Stallions usually urinate on the urine (scent mark) as they are exhibiting Flehmen (See Fig. 1).

Horses can distinguish the skin odors of one horse from another (Peron et al. 2014). Although they can distinguish their own feces from those of other horses they do not distinguish those of familiar from unfamiliar horses. They sniff most at feces from horses that are aggressive to them (Krueger and Flauger 2011). Mares can discriminate the urine of different individuals (Hothersall et al. 2010).

Wild stallions use manure piles, or stud piles, along well-used pathways, possibly to scent mark. These piles or middens may separate bands of horses both spatially and temporally. Even in a pasture, stallions and some geldings select one place to defecate and then back into the pile to eliminate, so the pile does not grow much wider. On the other hand, mares and most geldings face outward, gradually increasing the diameter of the pile. Because horses do not eat grass contaminated with feces, a pasture containing mares and geldings rapidly becomes “horsed out” or inedible.

Horses are also able to match the neigh of another horse with its picture (Proops et al.

2009). This is an example of cross-modal identification. Horses can learn to recognize human faces and are able to discriminate members of a pair of identical twins. They can transfer recognition from a two-dimensional photograph to a real person (Hothersall et al. 2010). They can match the appearance and smell of a familiar person with his or her voice (Lampe and Andre 2012). Perhaps most interesting is that horses respond differently to happy versus angry faces. They tend to look at the photograph of an angry face with their left eye, indicating right brain lateralization and their heart rate increases faster than it does to a photograph of a happy face (McComb et al. 2016).

## Donkeys

### Vocalizations

Donkey vocalizations are: the bray, grunt, growl, whuffle, and snort. The bray is performed by territorial males in the mornings, upon meeting other male donkeys and at mating. It carries for several kilometers. In agonistic encounters, the bray often begins with a “grunt” or “growl” followed by a very long exhalation and then a series of high-intensity noises. A single bray can last 24 s. In nonantagonistic greeting behavior, the bray is low intensity and ended with a soft atonal “whuffle.” The whuffle is used by mares searching for their foals.

The bray is used as a separation call by foals. The grunt is a short and the grumble a long vocalization, which are produced in antagonistic encounters. A snort is a short explosive sound given by an alert donkey; the sound does not carry (Moehlman 1998).

### Visual Signals

When alert the donkey’s head is raised and turned with ears forward and toward the intruder. When resting in the standing position, the donkey’s neck is almost horizontal, the ears are down and to the side, and the eyes are closed. Threats can vary from the subtle turning of the head by the sender, to adding ears back, head down, approach at a fast

walk, trot, or gallop, to opening the mouth, to actually biting the receiver.

#### Yawing

Donkeys, zebras, and the occasional horse mare exhibit an expression during estrus in which they open their mouths exposing their teeth and turn their ears to the side. Yawing may be an approach/avoidance signal.

#### Olfaction

Male donkeys defecate on fecal piles. These may be at the boundaries of territories, on long trails, and in the vicinity of water sources. In about half the occasions when a donkey encounters a manure pile he will sniff it, paw at it, Flehmen, and then defecate. Urination by one male facilitates urination by another.

#### Zebras

##### Vocalizations

There are species differences in vocalizations. Plains zebra bark whereas Grevy's zebra (*Equus grevyi*) bray like donkeys (King et al. 2016). Mountain zebras' (*Equus zebra zebra*) high-pitched whistling whinnies are given as an appeasement signal. Male Grevy's zebra emit a long "Arrr-Arrr" bray followed by a rising squeak during courtship and copulation (Rubenstein 2011).

##### Postures

When challenging another male zebra, the male will approach, engage, and withdraw. The zebra approaches with its head up and ears erect and at a brisk trot. At the final approach the head may be lowered but the ears are still up. The tail is lashed erratically. Zebras exhibit the arched neck threat at close approach. Once together they exchange olfactory information with naso-nasal and then nasogenital contact. When subordinate male zebras approach a dominant one, they open their mouths without baring their teeth and make chewing motions similar to snapping in foals (Joubert 1972).

**Perissodactyla Communication, Fig. 2** Flehmen by a tapir (2008)

#### Tapir

There are four species of tapir: Baird's (*Tapirus bairdii*), lowland (*T. terrestris*), mountain (*T. pinchaque*), and Malayan (*T. indicus*). The first three are South American and the fourth is Malaysian and remarkable for its distinctive half black, half white coat in comparison to the grey South American tapirs (Fig. 2).

##### Vocalizations

There are three types of call. A snort, a clicking sound made by the tongue and palate, and two shrill/squealing calls. One squealing call is high pitched and made in fear or appeasement and lasts 1.5–5 s. The second squeal is less noisy and is used during exploratory activity and mostly uttered by the dominant tapir. The clicking sound is used for individual identification (Hunsaker and Hahn 1965).

##### Postures

The large, rounded, and thick ears are moved constantly while feeding, whereas they are held upright and slightly forward when frightened (Medici 2011).

##### Olfaction

A tapir moves its proboscis constantly while active, perhaps to locate and identify food by smell and tactile stimuli, for the proboscis always elongates in the direction of food to be consumed.

##### Defecation

Tapirs defecate most frequently in water, but also along trails. Feces are loose and extremely

fibrous, with small squares of undigested leaf parts and pieces of twigs. After defecating the tapir, or specifically the Malaysian tapir, paws, covering the feces with twigs and leaves (Khan 2014).

### Urination

Tapirs, especially males, urinate frequently during the evening. The urine is projected backwards in a spray, which may be several meters long. Urine is often projected when the tapir appears to be annoyed. Urination occurs 3–5 times at interval of 20–50 meters.

## Rhinoceros

There are five species of rhinos: Greater One-horned Rhinoceros (*Rhinoceros unicornis*), the Javan Rhinoceros (*R. sondaicus*), the Sumatran Rhinoceros (*Dicerorhinus sumatrensis*), the White Rhinoceros (*Ceratotherium simum*), and the Black Rhinoceros (*Diceros bicornis*).

The white rhino is a grazer and lives on territories with several females and a dominant male and sometimes with subordinate males. These rhinos are the best studied because of their social structure and visibility on open grasslands.

The social structure of black rhinos is overlapping home ranges (Schenkel and Schenkel 1969). The males are usually solitary and the females live with their calves.

### Vocalizations

In white rhinos the Pant calls provide information about the caller's sex, age, and social situation (Cinkova and Policht 2015). In Indian rhinos the snorting sound (khaawk. . .khwaak) is given when approaching or being approached by another rhino. Honks are given in many agonistic interactions. Groans are emitted during face-to-face confrontations. Bleats and roars occur during courtship chases and fights. Rumbles occur during wallowing. Squeak-pants occur during courtship chases. Moo grunts are contact calls between cow and calf. The breeding call is a whistle-like sound (fleet. . .fleet) that may last for over a minute (Laurie 1982; Hazarika 2015; Table 1).

**Perissodactyla Communication, Table 1** Vocalizations of rhinoceros (Dinerstein 2011; Muggenthalrer et al. 2003)

| Species                  | Function of call                                                        | Name of call      |
|--------------------------|-------------------------------------------------------------------------|-------------------|
| Greater one-horned rhino | Approach of conspecific                                                 | Snort             |
|                          | Head to head aggressive encounters                                      | Honk              |
|                          | Submission and courtship                                                | Bleat             |
|                          | Intense encounters between females either with a male or another female | Roar              |
|                          | Males during courtship chases                                           | Squeal pant       |
|                          | Mother-offspring contact call                                           | Moo grunt         |
| Black rhino              | Confrontations                                                          | Growls            |
|                          | Confrontations                                                          | Trumpet call      |
|                          | Greeting and anger                                                      | Snort             |
|                          | Alarm                                                                   | Sneeze            |
|                          | Fear                                                                    | Wonk high pitched |
|                          | Terror                                                                  | Scream            |
|                          | Mother-offspring contact call                                           | Squeak            |
|                          | Peaceful                                                                | Mmwonk            |
| White rhino              | Contact call                                                            | Panting           |
|                          | Courting male                                                           | Hic-throb         |
|                          | Distress                                                                | Squeal            |
|                          | Agonistic                                                               | Bellow            |
|                          | Agonistic                                                               | Growl             |
|                          | Response to attack                                                      | Shriek            |
|                          | ?                                                                       | Infrasound        |
| Sumatran rhino           | ?                                                                       | Eep               |
|                          | ?                                                                       | Whale             |
|                          | Infrasonic "song"                                                       | Whistle bow       |

### Postures

The vigilance posture is head up, standing still, and ears rotating. The threat posture is an erect stance with erect pinna. The head is carried horizontally. During bull confrontations the animals will walk stiff legged, swing their heads from side to side, and thrash shrubs. They may rub their heads or horns on the shrub. They approach one another with upper lip curled and tail raised while

emitting screaming groans and rolling their eyes (Estes 1993). Baring the lower incisor tusks may serve as a visual display.

Dominance is signaled by a raised head with ears forward and staring. Submission is expressed with the head lowered and the ears back and the tail up.

### Olfaction

Rhinos of both sexes defecate on manure heaps (middening behavior). Before defecating, the rhino sniffs the manure pile then turns to eliminate followed by scraping with the hind limbs, which not only scatters the feces, but also creates two shallow ditches in the manure and the soil beneath, allowing males to spread their scent by means of manure caught in their hooves. Male feces are investigated more than female by both sexes and females investigate sub-adult feces more. Feces and urine can signal age, sex, and identity and reproductive stage to conspecifics and signals may persist for a month (Linklater et al 2013). Rhinos exhibit Flehmen in response to urine (Fig. 3).

### White Rhinos

A territorial male maintains 20–30 dung middens upon which he will always defecate, scattering the feces with slow kicking. Females and nonterritorial males will use the middens, but

not kick. Territorial males will visit a midden site sooner and be vigilant sooner in response to the odor of another territorial male. They will sniff more often and for longer periods in response to estrous female odor (Marneweck et al. 2017).

Only a territorial male sprays urine and does so only on his territory. First he will horn swipe a bush or the ground then scrape with all 4 ft then spray three to five times. Marking is most concentrated along territorial boundaries (Estes 1993).

Scents may be carried in the pedal scent glands. When urinating normally the urine falls down and back, but when squirt urinating the urine is released in four squirts aimed horizontally backwards. Squirt urination and foot-dragging displays are performed by breeding males only. Flehmen occurs during investigation of the cow by the bull.

### Conclusion

The Perissodactyl are a varied order. Some are solitary such as the tapir and black rhino. Most live in small groups in a fusion-fission pattern. Most are grazers, like equids and white rhino, but the black rhino and tapir are browsers. Their means of communication reflect this. The horses use their facial expressions to communicate to their herd mates. Vocal communication is especially important in mother young communication. The tapir appears to use mostly olfactory signs. All the Perissodactyl use feces on middens and urination to communicate, although the rhino do so much more dramatically than the equidae. All exhibit Flehmen See Figs. 1–3.

## Perissodactyla Diet

Kathryn A. Schoenecker

U.S. Geological Survey, Fort Collins Science Center, Fort Collins, CO, USA

Department of Ecosystem Science and Sustainability, Colorado State University, Fort Collins, CO, USA

Perissodactyla (Schoch 1989) includes tapirs, rhinoceros, wild asses, horses, and zebras. It is the order of hoofed mammals referred to as “odd-toed ungulates” because its members have one to three weight-bearing toes and walk on hoofs or “ungules.” They are herbivores that are specialized to exploit grasslands and brushy habitat (rhinos, horses, asses, zebras) or dense tropical forests (tapirs). All share a common digestive system called hindgut fermentation, or cecal digestion (in the cecum), and can consume relatively tough, coarse forage. Some perissodactyls are “browsers” that forage primarily on woody shrubs and trees, whereas others are “grazers” with a graminoid-dominated diet. They are all predominantly opportunistic feeders and select for quantity over quality of forage; that is, they consume more abundant low-quality forage instead of searching and selecting for higher-quality forage because it gives them the advantage of reducing search effort, which conserves energy.

Vegetation provides herbivores with protein, fiber, small amounts of water, and the nutrients needed to support their metabolism and survive. The minimum protein content required to meet metabolic functions in herbivores is ~6–7% (Owen-Smith 2002). Protein content is generally lower for grasses and sedges than forbs and shrubs, so in fall and winter, forbs and shrubs can potentially meet metabolic requirements better than graminoids. So although many perissodactyls are categorized as “grazers” and therefore consume mostly grass, they are able to subsist on non-graminoids as well. Khur in India have been observed eating seedpods (Shah 1993) and use hooves to break up woody vegetation to obtain succulent forbs at the base of woody plants. Wild

asses feed mostly on *Cyperus capillaris*, *Andropogon* spp., *Dichanthium annulatum*, *Aristida alsicansiouis*, and *Iseilema prostratum* (Jadhav 1979), but they also feed on tree leaves of *Salvadora oleoides* and *Salvadora persica* and leaves and pods of *Prosopis juliflora* (Smielowski and Raval 1988). Feral horse diets in New Mexico contain a lower percentage of grasses (50%) than studies of feral horse diet in other habitat types (Skasta et al. 2016; Hansen 1976), and feral burros are primarily browsers in Death Valley, California (Moehlman 1974). In three of seven annual diet studies, a native annual forb constituted the highest proportion (11%) of feral burro diets (Abella 2008), and shrubs can be the major component (58–84%) of feral burro diets, except in spring when they consume more forbs (Woodward and Ohmart 1976; Moehlman 1974).

Although perissodactyls try to satisfy energy demands (quantity) before quality of vegetation, they do forage selectively when higher-quality forage is easily available. Within a habitat-type, mountain zebras are highly selective, using only 7 of 17 grass species at feeding sites and 26% of plants available (Penzhorn and Novellie 1991). Out of 20 plant communities available in Mountain Zebra National Park, breeding herds preferred 9 in summer, 7 in winter, and 3 in both seasons, although bachelors showed no preference (Penzhorn and Novellie 1991). In Kenya plains zebras eat 6–7 species of grasses on average (Stewart and Stewart 1970), with zebras in South Africa eating 19 (Landman and Kerley 2001) to 27 species (Boyers 2011) displaying a seasonal change in species preference: 6 of 13 species preferred in the early dry season and 9 of 17 in the late dry season (Owen-Smith 2013).

Seasonal differences in perissodactyl diet are due to several factors. First, some plants are exclusively available during the wet season. Second, as more favored plants become less available during dry periods, perissodactyls such as rhinos may shift to less palatable species (Oloo et al. 1994). Third, some species may provide key resources during critical times such as succulents during drought. Finally, plants can differ in their relative palatability between wet and dry seasons, as well as different plant parts. This may be why rhinos

eat different plant parts during different times of the year (Oloo et al. 1994). Seasonal changes in the diet of *Equus* species are more likely due to changes in forage availability across summer and winter seasons (Crane et al. 1997; Hanley and Hanley 1982). In Hustai National Park, Przewalski's horses select a greater variety of vegetation classes in spring and autumn, less in summer, and only few in winter (King and Gurnell 2005). The diet of Asiatic wild asses across their range includes cereals and wormwood in summer, with proportions varying according to locale, conditions, and time of year, whereas in spring they feed on *Ephemerae*, such as *Poa* and *Bromus* (Bannikov 1971). Khulan (Asiatic wild ass) have a shrub-dominated C<sub>4</sub> diet in spring and fall and a grass-dominated C<sub>3</sub> diet in early summer and in midwinter (Horacek et al. 2012). Feral horse diet is generally consistent throughout the year; however, there are seasonal differences in specific grasses consumed or changes in the use of forbs during spring (Schoenecker et al. 2016).

Plants produce tannins and toxins to deter herbivory, called phenolic compounds. Ungulates that are categorized as grazers typically do not have the capacity to break down or detoxify plant phenolic compounds because these compounds are more common in browse species (Janis 1976). Thus, high amounts of phenolics in forbs and shrubs may deter grazing perissodactyls such as white rhinos and *Equus* species from feeding on them. Tannin-binding salivary proteins (TBSPs) that function to block the effect of plant toxins are produced in species that ingest tannins as part of their natural diet, such as black rhinos (Shimada 2006). Black rhinos can even induce production of TBSPs in saliva when they ingest greater amounts of plant toxins (Clauss et al. 2005a) to overcome toxic plant defenses.

Perissodactyls have varying requirements for surface water. White rhinos will drink daily or twice daily during the wet season when water is abundantly available, whereas in the dry season, they can reduce drinking to 2–4-day intervals (Pienaar 1994). Indian rhinos drink daily from streams, rivers, oxbow lakes, small puddles, and wallows, even some heavily contaminated with urine (Laurie 1982). Horses ingest approximately

30–50 mL water/kg body weight/day in both surface water and forage, and Indian rhinos are within the parameters for horses, having a daily water intake from 2.7 kg/day to 5.4 kg/day (Clauss et al. 2005b). In the dry season when standing water and seasonal streams are dry, rhinos feed near man-made reservoirs and in riverine habitat, which retains more water and has longer persistence of palatable herbs (Oloo et al. 1994). Khulan have higher water use efficiency than other equids and can exploit grassland pastures farther from water (Burnik Šturm et al. 2017).

## Tapirs

The family Tapiridae has five extant species which include Baird's tapir (*Tapirus bairdii*), Malayan tapir (*T. indicus*), little black tapir (*T. kabomani*), mountain tapir (*T. pinchaque*), and lowland or South American tapir (*T. terrestris*). Tapirs are browsers that inhabit dense tropical forests of South America and Asia. They feed on leaves, sprouts, stems, fruits and their seeds, aquatic plants, and some grasslike Poaceae and Cyperaceae species (Talamoni and Assis 2009). Tapirs are considered generalist herbivores, and the proportion of dietary items in their diet is closely attributed to what is available in their habitat. Thus, they are typically not "selective" feeders but more opportunistic (Henry et al. 2000), although some preference for certain plants has been observed (Talamoni and Assis 2009; Tobler 2002). The exceptions are the mountain tapir and Malaysian tapir which are more selective and choose certain favored plants regardless of their relative abundance in the habitat (Downer 2001; Meijaard and Strien 2003; Williams and Petrides 1980).

Tapirs have a broad and varied diet. The number of plant species they are known to feed on can be as high as 115 individual plant species (Williams and Petrides 1980; Hilbert et al. 2011) and ranging from between 8 and 50 different plant families depending on the region (Hilbert et al. 2011). In some areas, the diet of lowland tapirs is as high as 33% fruit (Bodmer 1990). Malaysian

tapirs prefer mostly woody plants from the families Euphorbiaceae and Rubiaceae (42%), whereas the recently discovered little black tapir feeds on palm leaves and seeds, but little else is known about its diet (Cozzuol et al. 2013). Baird's tapirs eat a high proportion of fiber from bamboo (40–55%; Tobler 2002). Tapirs are known to engage in geophagy, the deliberate ingestion of soil, as a way to obtain salt and minerals that may be deficient in the diet (Montenegro 1998).

Tapirs are considered important seed dispersers in the tropical forests they inhabit (Downer 2001; Galetti et al. 2001; Henry et al. 2000; Meijaard and Strien 2003). They ingest many seeds without crushing them with their molars, and even unprotected seeds survive passage in the tapir's digestive tract with germination rates of seeds in tapir feces similar to seeds from fresh fruits (Henry et al. 2000). Seeds of  $\geq 122$  different plant species have been identified in tapir feces in the Peruvian Amazon, illustrating the important role and facilitation of seed dispersal by tapirs (Tobler et al. 2010). Particularly for large seeds and palms (Palmae), which play a critical role in maintaining medium and large mammals during the dry season, a reduction or extinction of tapirs would deleteriously affect a substantial portion of native flora that sustains the ecology of the tropical forest.

## Rhinoceros

The family Rhinocerotidae is found in parts of Africa and Asia and is comprised of the black rhinoceros or "rhino" (*Diceros bicornis*), white rhino (*Ceratotherium simum*), Indian rhino (*Rhinoceros unicornis*), Javan rhino (*R. sondaicus*), and Sumatran rhino (*Dicerorhinus sumatrensis*). Rhinos inhabit dry savannas, grassland plains, wetlands, and dense forests in tropical and subtropical regions. The two African species have mouth adaptations to accommodate their feeding strategies: white rhinos are grazers with broad, square lips to facilitate exploiting short grass along the ground, whereas black rhinos are browsers with long, pointed lips for manipulating and gripping foliage

on shrubs and trees. Rhinos supplement their diet by licking or eating soil or rock material to obtain needed minerals, particularly sodium, potassium, calcium, and magnesium (Laurie 1982).

Black and Javan rhinos are exclusive browsers, whereas Sumatran rhinos are intermediate, switching between browse and grass depending on season and availability of plant species in their habitat (Dierenfeld et al. 2006). Black rhinos are selective browsers that forage on plants with low phenolic and alkaloid contents and high fiber, irrespective of protein content (Muya and Ogue 2000), although browse species that are more available in the habitat can be utilized more. However, black rhinos are also reported to select for high-quality forage with high crude protein content in other areas (Ganqa et al. 2005). Rhinos, like other ungulates, are confronted with a "cost" and "benefit" situation in which they have to balance the benefit of selecting for high-quality forage with the cost of search time and energy expended by such effort. For example, three species of plants accounted for more than 65% of the diet of black rhinos in three national parks in Africa, but browse availability only explained 14%, 15%, and 52% of diet selection, respectively (Buk and Knight 2010). Instead of diversifying their diet, black rhinos concentrate their feeding on a few species that have low plant toxins (Buk and Knight 2010). However, in general black rhinos have demonstrated a broad diet wherever they have been studied in Africa. *Acacia* species are important food plants comprising 27% of the diet in the wet period and 36% in the dry season, and the diversity of plants eaten is greater in the wet than the dry season (Oloo et al. 1994).

White rhinos are exclusive grazers of grasslands and even avoid herbaceous patches with too much forb cover. They focus on short-grass grasslands in wet months and shift to medium-tall *Themeda* grasslands as the dry season advances, and by late dry season, they move up to hillslopes to forage on tall-grass grasslands (Pienaar 1994). Indian rhinos, also grazers, feed on up to 183 different species of plants from 57 botanical families, but grass makes up a high percentage of their diet year-round (Pradhan et al. 2008), even as high as 70–89% (Laurie 1982). Indian rhinos will increase

browse intake in dry periods when grass is less available or when graminoids decline substantively in nutrition (Pradhan et al. 2008). Like other perissodactyls, rhinos have smaller ranges in areas with high vegetation diversity (Laurie 1982).

## Horses, Asses, and Zebras

The family Equidae occurs in steppe, semidesert, and desert environments (Schoenecker et al. 2016; Schultz and Kaiser 2013) and includes Grevy's zebra (*Equus grevyi*); plains zebra (*E. quagga*); mountain zebra (*E. zebra*); Asiatic wild ass also called khulan, onager, or khur (*E. hemionus*); Przewalski's horse (*E. ferus*); African wild ass (*E. africanus*); kiang (*E. kiang*); feral horse (*E. caballus*); and feral burro or donkey (*E. africanus asinus*). Equids are primarily grazers and are all very similar in their digestive physiology (Hummel et al. 2017). They are well adapted to low-quality forage (Janis 1976) with a total of 295 graminoid, herbaceous, and woody plant species identified as forage for *Equus* species (Schultz and Kaiser 2013). They select graminoids over other species when available (Schoenecker et al. 2016; see Table 4.1), yet each taxon has a specific spectrum of dietary plants. Przewalski's horse diet consists primarily of grasses, making up 75–83% of the diet even in winter (Siestes et al. 2009); however, when grasses are less available, they can utilize woody plants (Ganbaatar 2003). Feeding strategy of the Przewalski's horse is to satisfy energy demands with high quantity of forage and then secondly satisfy demands for higher-quality forage (Zang et al. 2017). The diet of kiangs is also made up of mostly graminoids, comprising between 84.3% and 100% of the diet (Harris and Miller 1995). Kiangs select for higher plant biomass and percent green foliage relative to random sites in the same habitats. At the plant level, kiangs select grasses over forbs and shrubs, whereas they select sedges in proportion to their availability during all seasons (St-Louis and Côté 2014).

Asiatic wild asses, have seasonally varied diets, foraging on up to 46 different species (Xu et al. 2012). *Stipa* is a major constituent of

khulan diet in spring and summer, with shrubs such as *Haloxylon ammodendron* and *Ceratoides latens* comprising up to 22% of khulan diet in winter (Xu et al. 2012). Khulan show strong seasonality with grazing in summer, mixed feeding in winter, and switching from one mode to the other in spring and autumn; their use of shrubs is more prevalent in winter (Burnik Šturm et al. 2017). Wild asses use water more efficiently (metabolically) than other equids and visit water sources primarily at night (Zhang et al. 2015) instead of during the heat of the day. Many truly desert-adapted species limit activity during the day to reduce heat loading and water loss and can sustain longer intervals between drinking.

The three extant species of zebras subsist predominantly on graminoids. Plains zebra diet consists almost entirely of grasses (Bodenstein et al. 2000; Venter and Kalule-Sabiti 2016), with occasional browse to maintain protein levels (Berry and Louw 1982). During the dry season, plains zebras spend more time foraging (Owen-Smith and Goodall 2014) and graze longer, taller grasses than in the wet season (Stelfox et al. 1986; Kleynhans et al. 2011). They select sites with lower levels of fiber than wildebeest or cattle (Voeten and Prins 1999) and even eat dry leaves (McNaughton 1985). They eat a broader range of species during the dry season than wet season to deal with limitations of reduced nutrition within dry season forage (Owen-Smith 2013). Plains zebra can be more exposed to diseases such as anthrax spores in soil during the wet season when they graze more intensively on short grasses and thus ingest more soil (Havarua et al. 2014). Mountain zebras are also tall-grass grazers, selecting greener grass with a high leaf/stalk ratio (Kraaij and Novellie 2010) and only including browse in their diet as quality and quantity of grass decline in winter (Penzhorn 1982; Novellie et al. 1988; Penzhorn and Novellie 1991; Weel et al. 2015). Grevy's zebras are predominantly grazers, although browse can comprise up to 30% of their diet during drought, and there can be significant variation in diet between individuals (Kleine 2010).

Major constituents of feral horse diets are graminoids, while forbs and shrubs play a more

limited, although sometimes still significant, role particularly in winter (Abaturov et al. 2016; Crane et al. 1997; Hansen 1976; Schoenecker et al. 2016; Skasta 2016). Grass species remain at or above 77% of feral horse diet in all seasons (Skasta et al. 2016) with sedges (*Carex* spp.) being consumed in bogs/meadows and stream sides (Crane et al. 1997) and shrubs making up only ~8% of the diet (Smith et al. 1998).

Donkeys, or feral burros, are the domesticated variety of African wild asses and evolved as a desert dweller able to survive in some of the harshest conditions on the planet. They retain many traits of their ancestors, able to live in areas with sparse vegetation, dispersed water sources, and widely fluctuating temperatures (Burden and Thiemann 2015). Feral burros feed on a wide variety of plant species, up to 39 different species in the Chemehuevi Mountains of California. However, as few as four plant species can comprise as much as 50% of the annual diet of feral burros (*Plantago insularis*, *Cercidium floridum*, *Prosopis* spp., and *Pluchea sericea*; Woodward and Ohmart 1976). They feed on fibrous plants; grasses comprise 66–76% of summer feral burro diets in the Cottonwood Mountains of Death Valley National Park (five times more than predicted based on their availability); however, burros switch to shrubs (50–81% of the diet) from September to April (Ginnett and Douglas 1982). *Muhlenbergia porteri* can be a substantial portion (24%) of July feral burro diets even though it is a very minor component of the plant community (Jordan et al. 1979). Feral burros are better adapted to low-quality diets than feral horses (Hummel et al. 2017) due to their lower energy and nutrient requirements, a greater potential for urea recycling (preserving metabolic water), and longer food particle retention in the digestive tract, which all serves to achieve higher digestibilities in burros (Hummel et al. 2017).

## Synonyms

Horse gait; Rhinoceros gait; Tapir gait

## Definition

Movements of the Perissodactyla (horses, tapirs, and rhinoceros) to transverse their environment.

The order Perissodactyla is composed of three families of odd-toed ungulates: Equidae, Rhinocerotidae, and Tapiridae (Pitra and Veits 2000). Within the Equidae family, there are eight extant species of horse, donkey, and zebra, whereas there are currently four living species of tapir and five rhinoceros (Wilson and Reeder 2005). The Perissodactyla are fully terrestrial and occupy a range of habitats. The equids inhabit grasslands, semi-desert, and desert-like environments (Schulz and Kaiser 2013), rhinoceros inhabit wet and dry grasslands (Sarma et al. 2011), and the tapirs inhabit various types of habitats ranging from very dry environments to wetlands to rainforests (Nowak 1991). The Perissodactyla are exclusively grass-eating animals classified as either grazers (eating vegetation at ground level) or browsers (eating from trees or bushes). For grazers, certain seasons may necessitate movements to find adequate food. For example, during the rainy season, zebras must migrate large distances in search of proper sustenance. Browsers, such as the rhino, are large and sedentary animals. They can find an adequate food supply year-round and therefore do not

need to migrate considerable distances (Mallet et al. 2019).

A defining characteristic of Perissodactyla is that they bear the brunt of their weight on their middle digit. This led to elongation and thickening of the middle toe and accounts for their mesaxonic symmetry. All present-day Perissodactyla have either one or three hoofed toes. The hoof itself contains wide and flattened bones that bear circular edges and are surrounded by a keratinous layer (comparable to the nails of claws) (Janis and Bernor 2019). The perissodactyls use unguligrade foot postures (walking on the toes) that serve to lengthen the legs, allowing for faster and more energy-efficient running (Janis and Bernor 2019). The tapir is unique in that it retains the structure of the ancestral tetradactyl perissodactyls and presents with four digits on its foreleg (MacLaren and McHorse 2020).

## Gait Sequences

Gait refers to the sequence that the limbs come into contact with the substrate. Within the perissodactyls there are numerous gait types largely driven by gait diversity in the equids (Andersson et al. 2012). To minimize discussion, we will only survey gait sequences observed in undomesticated perissodactyl species. Quadrupedal gaits in perissodactyls are usually categorized as symmetrical or asymmetrical based on kinematics. Symmetrical gaits occur when footfalls of the forelimb and hind limb are evenly spaced in time (e.g., walk, pace, or trot). Asymmetrical gaits (e.g., gallop and bound) occur when the actions of the forelimb or hind limb are unevenly spaced in time. All walking gaits in the perissodactyls are symmetrical and are defined by the sequence and coupling patterns by which animals move their limbs (Alexander 2003; Granatosky 2018). A lateral-sequence gait is one in which each hind limb footfall is followed by an ipsilateral forelimb footfall (i.e., right hind limb, right forelimb, left hind limb, and left forelimb). A diagonal-sequence gait is one in which each hind limb footfall is followed by a contralateral forelimb footfall (i.e., right hind limb, left

forelimb, left hind limb, and right forelimb). Commonly during walking gaits, the forelimbs and hind limbs are traveling together as a slightly asynchronous couplet. When the ipsilateral forelimbs and hind limbs are traveling together, this is referred to as a lateral-couplet; when the contralateral forelimbs and hind limbs are traveling together, this is referred to as a diagonal-couplet. Very rarely do the limbs move together in perfect synchrony (Granatosky 2018).

Lateral-sequence lateral-couplet footfall patterns tend to be most common in the perissodactyls and are assumed to be the best mechanism to prevent interlimb interference (Hildebrand 1965; Fig. 1). However, this footfall pattern is thought to be inherently unstable because a majority (~66%) of the stride is spent as a unilateral bipod (i.e., only two ipsilateral limbs in contact with the support), which tends to roll the body side to side throughout the stride (Cartmill et al. 2002). Lateral-sequence diagonal-couplet footfall patterns are observed in the tapirs. This footfall sequence is inherently more stable than lateral-sequence lateral-couplet gaits due to the generally low proportion of the stride spent as a unilateral bipod (~22%), and the relatively high proportion of the

stride spent as a diagonal bipod (only two contralateral limbs in contact with the support) and large tripod (three widely splayed limbs in contact with the support). In general, foot positions arranged as diagonal bipods and large tripods are thought to be highly stable (Cartmill et al. 2002; Granatosky 2018).

When it is necessary to increase locomotor speed, animals must transition into running gaits. Although it is commonly believed that the reason for a gait transition is due to maintaining a low-energy cost, it has been noted that other factors, such as reducing bone strain or low interstride variation, may play an important role in these transitions (Granatosky et al. 2018a; Wickler et al. 2003). The trot and pace are symmetrical quadrupedal runs. Running gaits include some period of the cycle in which no feet are touching the ground (i.e., an aerial phase). In trotting, diagonally opposite feet move in phase with each other; in pacing, the two feet on the same side of the body move in phase with each other.

At high locomotor speeds, the perissodactyls adopt asymmetrical galloping gaits. The two types of gallops are known as the rotary and traverse gallops. In horses and rhinoceros, the transverse gallop is most common. The transverse gallop is described as one forefoot being followed forward by the contralateral hindfoot, leading to a single flight phase with the lift off of the two forelimbs. Transverse galloping is mainly utilized by larger animals with longer forelimb segments and is additionally influenced by environmental and biomechanical factors (Biancardi and Minetti 2012). The rotary gallop is utilized most frequently by the tapirs (Hildebrand 1977). The rotary gallop is characterized by one forefoot moving forward followed by the ipsilateral hindfoot. This leads to a flight phase in between the two forefeet hitting the ground and the two hindfeet hitting the ground (Fig. 2).

**Perissodactyla Locomotion, Fig. 1** “Hildebrand” plot displaying phase against hind limb duty factor collected during quadrupedal walking in perissodactyls ( $n =$  seven species)

## Limb Loading

Due to the great size disparity and high-speed locomotion observed within the order, each of the species have developed somewhat differing

**Perissodactyla Locomotion, Fig. 2** Foot fall diagram representing the two types of gallops found in perissodactyls. LH = left hind limb; LF = left forelimb; RH = right hind limb; RF = right forelimb

biomechanical strategies to mitigate the high external loads acting upon their limbs (Mallet et al. 2019). In general, the forelimb of the perissodactyls bears more body weight than the hind limb and serves a net braking function (Dutto et al. 2006). Accordingly, bones of the forelimbs need to be reinforced in all directions to support higher masses in heavier animals. This is especially clear in the Rhinocerotidae. Mallet et al. (2019) explored interspecific variation in long bone morphology in extant rhinos using three-dimensional geometric morphometrics to elucidate how loading, phylogeny, and body mass influence osseous structures. Within the forelimb, the humerus demonstrates the clearest signal associated with loading regime. Across species, the humerus enlarges in the craniocaudal and mediolateral directions proportionally with the increasing mass of the rhinoceros. Furthermore, the lesser tubercle of the humerus has several vital functions in rhino locomotion. Its primary function is to promote greater shoulder stability and prevent hyperextension, which is accomplished by stabilizing shoulder articulation and providing a greater area for the medial end of the *m. supraspinatus* (a primary forelimb extensor and shoulder stabilizer) to insert (Mallet et al. 2019). Additionally, because of its relationship with the *m. supraspinatus*, the lesser

tubercle also acts as a medial lever arm for the extension movements of the forelimb. Moving distally, rhinos demonstrate an enlargement of the epicondyles of the humerus that provides a larger insertion area for the flexor and extensor muscles of the digits and enhances the stability of the elbow articulation (Mallet et al. 2019). Similarly, the distal trochlea of the humerus has an increased articular surface area to diminish the forces of proximodistal compression and mediolateral extension, thus allowing for posture to be maintained at high body masses (Mallet et al. 2019).

In all species of rhinoceros, most of their weight is carried by the proximal articulation surface of the radius, which expands medially and becomes asymmetrical in heavier rhinos (Mallet et al. 2019). Medi lateral weight distribution is enabled through the laterally expanding ulnar shaft. The medial development of the olecranon process of the ulna is related to larger insertions for the flexor muscles, which are essential to prevent wrist hyperextension (Mallet et al. 2019). Several characteristics in the forelimb are present that prevent wrist hyperflexion while enabling the massive rhinoceros to travel sturdily on multiple substrates. For example, there is an increased mediolateral wrist articulation freedom due to a

decrease in the styloid processes of the radius and ulna. Ultimately, this reduces the articular surface for the scaphoid and thus limits craniocaudal wrist flexion (Mallet et al. 2019).

The rhinoceros hind limb carries less weight than the forelimb, yet it has an essential propulsive function. As such, the anatomy of the limb is organized in a fashion to both amplify and resist these forces. The rhinoceros' femur is mediolaterally reinforced under the head and neck that has led to an enlargement of the medial condyle and epicondyle on the distal epiphysis (Mallet et al. 2019). The lesser trochanter is distally located along the femur, which provides the hip flexors have an improved lever arm (Mallet et al. 2019). The rhinos also have a mid-shaft third trochanter that is associated with a more distant and lateral greater trochanter. This anatomical arrangement allows for more vigorous hip flexion and abduction (Mallet et al. 2019). This contrasts sharply with horses and tapirs that have more proximal third and greater trochanters. As the greater trochanter is the insertion site for *m. gluteus medius* (the primary hip extensor), this anatomical arrangement in rhinos indicates that hip extension is less powerful than horses and tapirs (i.e., more cursorial perissodactyls) (Mallet et al. 2019). Finally, there is lateral torsion in the distal femur that results in a more laterally deviated position of the knee. This knee placement may improve weight-bearing by shifting the body mass laterally (Mallet et al. 2019).

In contrast to the massive size of the rhinoceros, the tapirs are smaller and have anatomy more consistent with cursorial locomotion, albeit not as specialized as the equids (MacLaren and McHorse 2020). The tapirs show a general narrowing in the mediolateral aspect of the long bones on the limbs. This reduces bone mass (and limb mass in general), which means that the muscles do not have to overcome as great of an inertial force to accomplish movement (MacLaren and Nauwelaerts 2016). The general musculature in the forelimbs of tapirs is akin to the horse; they differ mainly in their relative size and mass percentage (MacLaren and Nauwelaerts 2016). An

assessment of the physiological cross-sectional area (PCSA) of the muscles shows no notable differences between the *Tapirus* and *Equus* except for two muscles (i.e., *m. flexor carpi ulnaris* and *m. biceps brachii*). These muscles both presented larger in *Equus* are consistent with their high-speed cursorial locomotion (MacLaren and McHorse 2020).

The tapirs display a shallow glenohumeral cavity compared to other perissodactyls, which has been attributed to their use of the rotary gallop (MacLaren and Nauwelaerts 2016). This shallow cavity facilitates a higher degree of shoulder mobility and increases the parasagittal movement of the humeral head within the shoulder joint enabling tapirs to generate greater stride lengths (MacLaren and Nauwelaerts 2016). Together, the combination of a large supraspinous and associated *m. supraspinatus*, a shallow glenoid cavity, and a distal footpad equip the tapir to function well at high speeds (MacLaren and Nauwelaerts 2016). Tapirs also have humeral flexors inserted in a notably proximal manner to the joint center. This proximal muscle insertion results in a shorter lever arm for *m. teres major* and *m. deltoideus* that allows for decreased torque, rapid flexion of the shoulder, and rapid adduction of the humerus (MacLaren and Nauwelaerts 2016).

Merkens and Schamhardt (1994) analyzed kinematics and the ground reaction forces occurring in the fore- and hind limbs of horses during different gait patterns with force plates and kinematic analysis assisted by the presence of photodiodes (tracers) on the limbs. They found that the ground impact occurring during walking and trotting were similar in each limb, but that overall, the forelimbs had a higher ground force reaction than the hind limbs. Forelimbs carry approximately 60% of the body weight at rest and have greater vertical forces when moving (Merkens and Schamhardt 1994) (Fig. 3). However, the hind limbs experience greater horizontal forces during locomotion, as they generate more of the propulsion for the animal (Granatosky et al. 2018b).

During locomotion, high external forces act to hyperextend the fetlock joint in horses.

### Perissodactyla Locomotion,

**Fig. 3** Force plate recording of the horizontal (red) and vertical (blue) ground reaction forces of the right fore- and hind limb at walk (top panel) and trot (bottom panel). Data from Merkens and Schamart (1994)

Hyperextension of the fetlock joint causes high levels of stress in the *m. interosseus medius* (suspensory ligament) and deep digital flexor and superficial digital flexor tendons. The high forces get built up within the tendons as stored potential energy, allowing the limb to act in a spring-like manner, releasing the stored energy as kinetic energy for high-efficiency gaits. However, the high stresses in these tendons increase with speed, and thus, the tendons become more prone to injury with increased speeds (Harrison et al. 2010).

### Perissodactyl Locomotion and Medicine

For millennia, horses have been an essential part of human existence. Their earliest use was for

meat consumption, but they eventually became necessary for transportation and efficient farming (Hausberger et al. 2018). With the onset of modern industrialization, horses transitioned from a necessity into a luxury, as they are now primarily used for entertainment through horse racing and casual enjoyment in horseback riding (Hausberger et al. 2018). One use that has been gaining more traction lately is the use of horses in hippotherapy (Koca 2016). Horses, like humans, have a tri-axial movement pattern of the pelvis and can consequently simulate this movement pattern in patients when they are placed on the horse's back (Koca 2016). The goal of this therapy is to utilize this similar movement to provide motor and sensory input during physical therapy (Koca 2016). The natural gait of horses encourages anterior and posterior swinging movements, the

development of the patient's paraspinal muscles, and affects the bones of the patient's pelvic girdle two times more than the gait of the patient alone (Koca 2016). Hippotherapy has been shown to decrease recovery time in patients, as well as improve their balance, posture, and muscle control (Koca 2016). Clinical trials have demonstrated efficacy in patients with multiple sclerosis, cerebral palsy, autism, and those recovering from a stroke (Koca 2016).

## Conclusion

The Perissodactyla order is composed of the families Equidae, Tapiridae, and Rhinocerotidae. The defining characteristic of Perissodactyla is that they have either one or three hoofed toes and bear the brunt of their weight on their middle digit. All species use symmetrical and asymmetrical gaits and transition through standard mammalian gait patterns as speed increases (i.e., lateral sequence lateral-couplet and lateral-sequence diagonal-couplet gaits during walking, trotting, or pacing during medium speeds, and rotary or transverse gallops during high speeds). The large size disparity within the order has resulted in highly variable limb loading and anatomy across the species. Although the large mass of the rhinoceros is not particularly well suited to speedy gaits, its massive size is an advantage against predators and thus rhinoceroses have developed osteological features to support their large mass. More primitive and significantly smaller than the horse, tapirs have more simplistic anatomy; however, this anatomy has efficiently evolved to enable tapirs to escape predators through their rotary gallop. The horse has evolved several elastic strain adaptations to help facilitate and mitigate the high external loads experienced during cursorial locomotion. The perissodactyls, especially the horse, have had a long history with human. Starting out as a food source, the horse transitioned into a means of transportation and now serves as a medical tool to help patients regain mobility.

Temperament

### Introduction

What is personality? If asked this question, most people would have an intuitive sense of what the word “personality” means. When describing their pets, or animals at zoos, it would not be uncommon for someone to use terms such as curious, excited, or shy. However, pinning down a clear definition of personality is more challenging. In humans, personality refers to individual differences in patterns of thinking, feeling, and behaving (Gosling 2001). These patterns are thought to be stable across time, meaning that a person who tends to be excitable at one time point will also tend to be excitable a month later, although there are known changes that occur across a person’s life span (Roberts et al. 2006). Individual patterns are also thought to be stable across contexts. For example, someone who is curious about new people will also be curious about new aspects of their environment. It is unfortunately not possible to ask an animal how they are thinking or feeling. As a result, the most commonly used definition of animal personality is individual differences in behavior that are consistent across time and contexts (Gosling 2001). Despite this, researchers have often shied away from labeling individual

differences in behavior as “personality,” for fear of anthropomorphism (Gosling and John 1999). Instead, labels such as behavioral syndromes and temperament have been used interchangeably with personality. However, there must be measures that do not rely on verbal reports of thoughts or feelings, as personality has been repeatedly assessed in young children who are yet to develop language abilities (e.g., Thomas and Chess 1977). So, if we cannot ask an animal, or child, about their personality, what methods can we use?

### Measuring Animal Personality

The methods used to study animal personality can be categorized using two main criteria: the way in which measures are selected or the data collection method. Using the former criterion, methods can be distinguished as either predominantly top-down or bottom-up. Bottom-up procedures involve selecting measures that are specific to the studied species, therefore maximizing the likelihood of including relevant traits (Weiss and Adams 2013). However, this does mean that cross-species comparisons are made more challenging, due to the variation in measures used in different studies. In contrast, top-down approaches adapt an existing model to create a measure for assessing another species (Freeman et al. 2011). This does run the risk of including traits that are irrelevant outside of the original model, but facilitates cross-species comparisons.

When using a top-down approach, a commonly adapted framework is the Five Factor Model (Goldberg 1990). This is a widely accepted model for human personality, and as the name suggests, it consists of five factors: Openness to Experience, Conscientiousness, Extraversion, Agreeableness, and Neuroticism. In this model, an individual with a high score on Openness to Experience tends toward traits such as imagination, creativity, and curiosity, while individuals who are self-disciplined and dutiful score highly on the Conscientiousness factor. The Extraversion factor describes an individual’s tendency to be

sociable, assertive, and active. Agreeableness contains traits such as trust, cooperation, and a lack of aggression, and finally, vulnerability to stress, anxiety, and depression describe the high pole of the Neuroticism factor.

The animal personality literature suggests that factors analogous to all of the human five factors are found in other species (Gosling and John 1999). In the most recent comprehensive review to date, a factor similar to Extraversion was found most frequently, in 90% of studies, across taxa as diverse as chimpanzees and octopuses. Analogues to Neuroticism and Agreeableness were almost as common, with all three of these factors emerging in cats, dogs, rhesus monkeys, gorillas, and chimpanzees. Openness-like dimensions were present in 7 of 12 species, which was at least partially attributed to methodological issues. Finally, although both cats and dogs possessed a factor combining Conscientiousness and Openness, only chimpanzees exhibited a pure Conscientiousness factor. Overall, this suggests that shared, general mechanisms may be responsible for the personality dimensions of Extraversion, Neuroticism, Agreeableness, and potentially Openness, although the specific behavioral manifestations of each differ between species. In contrast, Conscientiousness may be relatively young in evolutionary terms, shared only by humans and our closest phylogenetic relatives.

Although there appears to be a considerable number of personality traits shared across species, there are clear species-specific differences in how these are manifested in behavior. For example, a cuttlefish classed as bold, similar to one facet of human Extraversion, spends more time at the top of the tank and produces a visual threat display in response to a predator (Carere et al. 2015). In contrast, an extraverted bottlenose dolphin may vocalize often and engage in a variety of play behaviors (Highfill and Kuczaj 2007). It is therefore important for specific features of any species to be carefully considered when assessing their personality. For instance, to assess aggressiveness as a personality trait in dolphins, it would be inappropriate to include the skin color threat displays seen in cuttlefish (Carere et al. 2015), but

relevant to measure biting or ramming (Connor et al. 2000).

Instead of top-down versus bottom-up categorization, animal personality methods can be distinguished based on the method of data collection, of which there are two main types: behavioral coding and trait rating. Behavioral coding involves making observations of animals and recording the occurrence of behaviors of interest. Where naturalistic coding is used, animals are observed without any human intervention or manipulation, which can be in a captive or wild setting (Freeman et al. 2011). For example, the behavior of harbor seals and California sea lions has been recorded without experimenter interference (de Vere 2017). Using the frequencies of these behaviors, both species demonstrated two personality factors: boldness and routine activity. Bold seals and sea lions were active, alert, and more likely to move around on land, while highly routine individuals tended to swim in predictable patterns and rest little. In contrast, experimental coding involves making observations during behavioral tests. For example, hermit crabs have been assessed for personality using two tests: predator and open field (Watanabe et al. 2012). The responses of individual crabs were described using two behavioral dimensions. The first, named shy-bold, consisted of the time taken for crabs to emerge versus hide in response to a predator. The second dimension was named exploration-avoidance, as it contained the measurements of exploration in a novel environment, the open field, and the time taken to emerge after the predator was removed.

The main alternative, trait rating, involves people judging individual animals on their tendencies on a number of trait words, such as curious or active. These judgments may be based on a rater's cumulative experience with the focal animal, as in the case of pet owners or zoo keepers (Freeman et al. 2011). An example of this can be seen in a personality assessment of bottlenose dolphins (Highfill and Kuczaj 2007). The dolphin population was housed at a facility where trainers were responsible for their daily care. These people rated the dolphins on traits such as reliable, curious, and

playful, revealing individual scores that paralleled those found in humans (Goldberg 1990). Alternatively, judges may rate animals after having made a certain set of observations. For example, this design has been applied by having judges rate individual horses on traits such as exploration, vigilant, and submissive, after observing 2 hours of their behavior (Lloyd et al. 2007). This revealed six factors that explained the variation in ratings between horses, one of which was named sociability, as it consisted of traits such as sociable, playful, and popular.

## Why Do We Care About Animal Personality?

### Welfare

Now that we know that animals have personality, you may be wondering: why do we care? Well, personality has been linked to several interesting areas of research. One of the most important of these for the animals themselves is welfare. Commonly used indicators of poor animal welfare are stereotypic behaviors, which are defined as those that are repetitive, unvarying, and functionless (Mason and Latham 2004). Given that these behaviors are estimated to be exhibited by more than 85 million animals globally (Mason and Latham 2004), it is important to understand the contributing factors, and growing evidence suggests that one of these is personality.

In one example of this, an interaction was found between rearing conditions and personality. Highly gentle or nervous 4-month-old rhesus macaques who were reared in indoor cages were more likely to exhibit stereotypic behaviors later in life (Vandeleest et al. 2011). The same effect was not seen for nervous or gentle macaques reared outdoors, therefore underscoring the subtle influence that personality can have on welfare outcomes. In another taxon, personality has also been found to mediate the effects of changes in environmental conditions. Parrots rated as highly extraverted developed fewer stereotypic behaviors while living in a barren environment (Cussen 2013). Low extraversion birds also maintained a higher level of stereotypies even after being

reintroduced to a more complex, enriching environment.

However, there are issues associated with using stereotypic behaviors as indicators of poor welfare. One of these is that not all personality types seem to react in the same way to negative environments. A personality dimension along which animals can be characterized is the proactive-reactive axis. Proactive animals respond to stressful stimuli in an active manner, such as by exhibiting stereotypic behaviors. In contrast, those with reactive personalities are more likely to show passive responses, resulting in fewer stereotypic behaviors, despite exhibiting more drastic physiological markers of stress (Ijichi et al. 2013). Therefore, of two animals not exhibiting stereotypic behaviors, one with a reactive personality is more cause for concern than one with a proactive personality. Consequently, knowledge of animal personalities could allow welfare measures to be individualized for maximal well-being.

Personality is also associated with the extent to which animals interact with environmental enrichment. Although definitions of enrichment have changed over the years, a broad definition is increasing the choices available to animals and encouraging species-typical behavior by providing physical, mental, and social stimulation (Kulpa-Eddy et al. 2005). Improving animal welfare is frequently cited as the primary function of providing environmental enrichment, but the needs and preferences of individual animals are often not taken into account.

Most of the evidence suggesting that personality mediates the effectiveness of various types of enrichment comes from studies of chimpanzees, involving research or training participation. In one such study, cognitive tasks involving selecting answers on a screen were thought to be potentially enriching. However, even when these tasks were familiar, chimpanzees characterized as stress sensitive exhibited increased self-directed behaviors, such as scratching, after providing an incorrect answer (Yamanashi and Matsuzawa 2010). High scores on the Openness personality dimension have also been associated with voluntary participation in potentially enriching interactions with humans. For example, high-Openness

chimpanzees chose to spend more time engaged in research activities (Herrelko et al. 2012), as well as successfully completing a voluntary medical sampling procedure in the first session (Reamer et al. 2014).

In a study of a different species, snow leopards, novel objects were provided as a form of environmental enrichment. Leopards who visited these objects more also scored highly on one or both of the personality dimensions of Active/Vigilant and Curious/Playful (Gartner and Powell 2012). This provides two potential implications for using novel objects as enrichment for these animals. Firstly, novel objects may not be effective for providing enrichment for leopards with low scores on Active/Vigilant and Curious/Playful. Secondly, individuals with high scores on these dimensions may visit the objects more and therefore derive greater enrichment value from them. However, they may also become bored faster and require more frequent changes in enrichment provisioning to maintain potential welfare benefits.

Finally, several authors have made suggestions for individualized housing provisions, based on personality assessments. For example, cheetahs with high scores on the tense-fearful dimension were rated as being fearful, insecure, and tense (Wielebnowski 1999). As a result, it was suggested that providing ample access to hiding places, out of reach of disturbances, might disproportionately benefit these individuals. Similarly, shy cuttlefish, who responded most passively and with the least threat behavior toward a predator, may require housing that shelters them from observers (Carere et al. 2015). Lastly, there is emerging empirical evidence to support such suggestions; for example, gorillas with high understanding scores seem to react more negatively to the presence of large crowds of visitors, as they performed more undesirable behaviors under these conditions, including stereotypies (Stoinski et al. 2012). Personality therefore has a large range of potential influences on the welfare animals experience, as well as our measures of it. Expanding our understanding of these effects can help us provide the animals under our care with the best possible welfare.

## Learning and Problem Solving

Personality has also been linked with individual variation in learning performance and problem solving, which is significant for several reasons. First, animal models are often used to inform our knowledge of the general mechanisms underlying learning and cognition. Ruling out any variation caused by confounding factors, such as personality, is therefore important for determining the true effects of experimental manipulations. Secondly, animal in many settings, such as pets, working roles, and veterinary check-ups, often need to be trained on specific behaviors. It is therefore useful to understand the influence of personality on training success, as this can facilitate the use of the most effective techniques for each individual.

The personality trait of exploration has been frequently assessed in relation to learning performance. For example, exploration types in rhesus macaques were associated with training success on a positive reinforcement task (Coleman et al. 2005). This type of training is commonly used in the management of captive populations. In this case, animals learned that a clicker sound was associated with being rewarded with a food treat from the trainer's hand. The monkeys then heard the clicker and received a reward if they touched a target hung outside their cage. Training was considered successful if over three consecutive 10 min sessions, the individual performed the behavior on command at least 3 times. Exploratory monkeys, who approached and investigated novel food, were all successfully trained on the task, whereas only half of the individuals who never investigated the item were successfully trained.

Similar results have been found in other species. Ravens were assessed for their exploratory tendencies by measuring their latency to investigate a novel object, a bottle (Range et al. 2006). First, animals watched the experimenter place food inside a bottle. They were then given access to the bottle, which they had to manipulate to access the reward. More exploratory ravens were fastest at learning to solve this problem, primary due to initially approaching the bottle faster. Parallel results have been found in mice, in which more exploratory individuals were those who

investigated more open areas in a novel environment (Matzel et al. 2003). Mice who exhibited this tendency also demonstrated more efficient learning on several different learning tasks: discriminating between rewarded and unrewarded odors, suppressing movement when exposed to an unpleasant stimulus, accuracy in locating a reward in a maze, and time taken to locate a hidden platform in a pool of water. One possible explanation for such findings is that exploratory individuals are simply more likely to encounter opportunities for learning, as they will be more likely to investigate novel environmental features (Sih et al. 2004).

Emerging evidence implicates other personality dimensions in specific aspects of learning abilities. In one study, rhesus macaques were trained on a serial chaining task, which requires a series of stimuli to be selected in the correct order. Initially, the item list is learnt by trial and error, with a food reward provided for a complete correct response (Altschul et al. 2016). Macaques rated as high on friendliness and openness personality dimensions exhibited lower error rates, and made better progress, meaning that they made it further through the list in the correct order before making an error or completing the sequence. More specifically, friendliness was associated with consistently better performance over time, while high openness was associated with faster rates of learning.

Finally, there is tentative research suggesting that certain personality types are associated with greater innovation and creativity, and therefore more efficient learning. Pigeons were assessed for neophobia, a common measure of the bold-shy axis, by measuring the time taken to feed when a novel object was placed next to their food dish (Bouchard et al. 2007). Birds who exhibited lower neophobia were more innovative in opening a problem box, thus facilitating faster task completion. These individuals also required fewer demonstrations by a conspecific to learn how to remove a stopper from a tube containing food, therefore exhibiting faster social learning. Bottlenose dolphins also show individual differences in the ability to mentally plan their behavior, leading to differences in the extent of trial and error required to solve problems (Kuczaj and

Walker 2006; Kuczaj et al. 2009). Furthermore, the behavior of bold dolphins is more likely to be copied by other individuals (Kuczaj et al. 2006; Kuczaj and Yeater 2006). This is particularly interesting, as it suggests that differences in learning and problem-solving abilities may not only be related to one's own personality but also to that of those around you.

### Friendships

Like humans, members of many other species have friends. Unfortunately, we cannot ask a chimpanzee who they are friends with, but we can measure who they choose to spend time with and what they do during this time (Weinstein and Capitanio 2008). Personality seems to influence who become friends in the first place, and potentially one's satisfaction with these relationships over time. In rhesus macaques, affiliative behaviors tend to be performed most between related individuals of the same age and sex. However, when these factors were taken into account, individuals initiating affiliative behaviors with each other tended to have similar scores on two personality dimensions: adaptability and equitability (Weinstein & Capitanio 2008). Similarly, even when sex and age effects were accounted for, chimpanzee friends tended to have similar sociability scores (Massen and Koski 2014). In this study, the chimpanzee sociability personality dimension contains descriptors such as many animals sitting close by, and the frequency of grooming received and given, both of which are known affiliative behaviors. Chimpanzee sociability has significant parallels with human extraversion (Goldberg 1990), which human friends also tend to score similarly on (Nelson et al. 2011). Another primate study also found support for this extraversion-friendship link, with capuchin pairs demonstrating higher quality relationships if they had similar sociability scores (Morton et al. 2015).

Although research examining links between animal friendships and personality has predominantly focused on primate species, it is likely that similar associations are present in other taxa. For example, recent evidence demonstrated that three personality factors – extraversion,

conscientiousness, and neuroticism – influence the quality of bonds formed between pairs of bottlenose dolphins (Moreno 2017). Dolphins had the most positive bonds when each individual in a pairing scored similarly on the conscientiousness factor. This parallels the role of conscientiousness in human relationships; both teenager friendship quality (Jensen-Campbell and Malcolm 2007) and adult friendship satisfaction (Wilson et al. 2015) are associated with conscientiousness scores. Interestingly, the opposite pattern was true for extraversion and neuroticism. Pairs of dolphins who were dissimilar in their scores on these personality dimensions had the most positive bonds (Moreno 2017). Both similar and dissimilar extraversion scores have been associated with human friendships during college (Nelson et al. 2011), suggesting that bottlenose dolphin friendships may have specific features that facilitate dissimilar scores to a greater extent. The association between dissimilar neuroticism scores and dolphin bond quality (Moreno 2017) contrasts with findings in capuchins, in which relationships were more friendly and affiliative between individuals who were similar in neuroticism (Morton et al. 2015).

The maintenance of friendships over time may also be affected to some extent by personality. For example, not all rhesus macaque friendships are maintained in the long-term. The more similar friends' equitability scores were at 1 year old, the greater the likelihood of those macaques still being friends 1 year later (Weinstein and Capitanio 2012). However, current evidence suggests that personality similarity or dissimilarity may be most important in the forming of friendships and then that other factors may become more important over time. This is consistent with findings in humans, in which personality has a greater effect on the formation of friendships, compared to their maintenance over time (Hartup 1996; Nelson et al. 2011).

### Human Disturbance

Personality may influence the extent to which individual animals are affected by human activities, such as wildlife tourism and urbanization. Firstly, while the former provides the potential

for educating people about the natural environment, the public's high demand for this access to wildlife exposes animals to far greater levels of human disturbance than ever before. It has been suggested that individuals differ in their tolerance of these anthropogenic disturbances (Bejder et al. 2009). Depending on this tolerance level, some animals may suffer more severe consequences than others. For example, more sensitive animals may be immediately displaced upon the onset of human presence, while others may remain in the location. However, even those who remain may have personality characteristics that alter their behavioral reactions. Some animals seem to habituate to human presence, meaning that over time their response to humans decreases, whereas others become sensitized and exhibit more extreme behavior each time they are disturbed (Bejder et al. 2009). Furthermore, once human presence is no longer novel, it is difficult to assess the extent of our impact, as animals with low tolerance levels have already been displaced.

An empirical example of the effects of personality on initial response and subsequent habituation to human disturbance comes from yellow-eyed penguins. This species is endangered and found only in its home country of New Zealand (Ellenberg et al. 2009). Penguins were categorized into three personality types based on their response to a person in close proximity: timid, calm, and aggressive. Each penguin was then assessed for habituation to human disturbance over five days, during which an experimenter approached the nest once per day. On the first day, the heart rates of calm and timid females took the longest time to return to baseline levels after human approach. Over the duration of testing, there was negligible change in the heart rate recovery time of aggressive birds. However, for calm birds, both recovery time and the maximum heart rate induced by the disturbance decreased. This reduction in reaction across repeated exposure indicates that habituation to human disturbance occurred only in birds with calm personalities. Such findings are of great importance for understanding the impact of well-meaning wildlife tourists, particularly for severely threatened species.

Not all sources of potential disturbance by humans come from tourism. Indeed, increased urbanization has the clear side effect of impacting animal populations. This provides the potential for benefits, such as new food sources and warmer temperatures, but also costs, such as increased potential for exposure to urban predators (Sol et al. 2013). Not all animals are equally suited for expanding into these urban environments, and it has been suggested that those of certain personality types, such as exploratory and bold, are most likely to reach more distant habitats and/or arrive first in a new habitat (Sol et al. 2013).

In support of such suggestions, some differences have been found in the personalities of birds inhabiting rural versus urban environments. In one study, personality was assessed in house sparrows from four locations varying in their extent of urbanization (Bokony et al. 2012). The four traits measured – object neophobia, food neophobia, risk taking, and activity – formed one broader personality dimension in birds from the rural locations. In urban sparrows, food neophobia (avoidance of novel food) remained a separate trait. A potential explanation for this finding is that sparrows inhabiting urban locations may have more food sources to choose from, thus relaxing the selection pressure experienced by rural birds. There were also more birds in the urban sample exhibiting very avoidant responses in the predator test. This may represent an advantageous adaptation, due to their increased exposure to one of their predators, the sparrowhawk.

Negative features experienced within urban environments also do not seem to have the same effects on all personality types. In great tits, parents altered their nesting behavior in response to anthropogenic noise differently depending on their personality (Naguib et al. 2013). Parents of both sexes took longer to enter nest-boxes while urban background noise was played, and sex-dependent effects were also found; when noises were played, bold, fast-exploring females and shy, less-exploratory males reduced the frequency of visits to their nest-boxes. Such findings emphasize the complex relationships between anthropogenic impacts, personality, and a range of other factors. As our impact on the natural world

increases, it is important to consider the characteristics of nonhuman animals at each level: species, population, and individual.

## Conclusion

Aside from being an interesting topic of research in its own right, the study of animal personality has far reaching implications and applications. For example, for pet owners, whether a new addition will assimilate well into the existing pack can often be a concern. Perhaps by knowing about the personality of your pets, you could maximize their chances of making friends. On a more serious note, there are millions of animals under human care around the world (Mason and Latham 2004), from pets, to zoo and aquarium animals, to research subjects. We therefore have a responsibility to provide these animals with the best possible level of care. As has been discussed here, personality has been linked with common measures of poor welfare, such as both the presence and absence of stereotypic behaviors (Mason and Latham 2004). Traits such as exploration (Range et al. 2006) and boldness (Bouchard et al. 2007) have also been associated with success in training animals on various learning tasks, which can be used to provide animals with individualized attention. Finally, increasing our knowledge of the differential impacts of human presence on animals with varying personalities can benefit both our own interactions with the natural world and the well-being of the animals we live alongside.

## Introduction

Positron emission tomography (PET) is a medical imaging technique used to visualize and measure physiological processes by administering a radioactive substance, known as a tracer, to living animals. The tracer spreads and accumulates in the body, producing gamma rays that are detected by the PET scanner and used to form an image of the tracer's distribution. PET images are usually combined with other imaging techniques that better visualize anatomical details, such as computed tomography (CT) or magnetic resonance imaging (MRI).

## Physics

The excess protons in the nuclei of some unstable isotopes are released and turned into a *positron*, a neutrino, and a neutron in a process known as  $\beta^+$  decay. Positrons are particles with the same mass as electrons but the opposite (i.e., positive) charge. When released from the nucleus, they travel a short distance (a few millimeters) within the body, colliding with surrounding atoms and rapidly losing kinetic energy. They then combine with an electron to form a positronium that decays through *annihilation*. In this process, the particle's mass disappears and its energy is released as two gamma-ray (short-wavelength, high-energy) photons traveling in opposite directions (at  $180^\circ$  to each other).

The basic function of a PET scanner is to count the number of these released photon pairs. They are absorbed by scintillation crystals arranged like a ring within the PET scanner (collectively known as the “camera”). The crystals convert photons into visible light and then into an amplified electrical signal and are usually made of either bismuth germanate (BGO) or cerium-doped lutetium oxyorthosilicate (LSO).

## Image Production

The detection of two released photons almost simultaneously (within about 4–10 ns of each other) by the scintillation crystals is known as a *coincidence* and is the basis of image formation in PET. Nuclear decay occurs somewhere along the straight line connecting the two scintillation crystals that detected the released photons (the *line of response*). Therefore, the detection of millions of these coincidences allows precise spatial localization and reconstruction of a cross-sectional PET image using the mathematical principles of computed tomography.

When two photons released from the same annihilation event traveling at  $180^\circ$  to each other are detected, a *true coincidence* is said to have occurred. Three other types of events, collectively known as *false coincidences*, degrade both image quality and the accuracy of PET quantification.

These include *random coincidences*, which occur when two photons from separate positron-electron annihilation events are simultaneously detected; *spurious coincidences*, which result from photons produced by mechanisms other than annihilation; and *scatters*, when one of the photons undergoes *Compton scatter* and deviates from its intended path. Compton scatter, caused by interactions between photons and surrounding electrons, changes both the direction and energy of the emitted photons, resulting in coincidences being missed and ultimately reducing signal – a phenomenon known as *attenuation*. In a typical human PET experiment, attenuation affects the vast majority of photons by the time they reach the detectors, and affects photons originating from close to the center of the body more than those released peripherally.

The size of the scintillation crystals determines the spatial resolution of a PET image, which is typically between 2 mm and 5 mm in clinical PET scanners. Other factors include *noncollinearity* of the annihilated protons (the situation where positrons are annihilated before they come to a complete stop, have residual kinetic energy, and thus produce photons that are not emitted at an angle of exactly  $180^\circ$ ) and how far the positrons travel through the tissue before annihilating (*positron range*).

A single scintillation crystal is unable to distinguish two photons resulting from separate coincidences if they occur too close together in time; in this situation, two coincidences may be detected as one. In addition, the electronics of the PET camera can only process and transmit data at a certain maximal rate. These two factors result in some coincidences going undetected, known as *dead-time losses*. These losses can be reduced by using cameras with more scintillation crystals.

## Radiochemistry

*Tracers* are substances that can track biochemical or physiological processes without perturbing them. For this purpose, they are *labeled* using positron-emitting radioisotopes, which are

produced in a particle accelerator (*cyclotron*) by bombarding stable nuclei with a beam of protons that become part of the nuclei. Radioisotopes of elements found in biologically relevant compounds, such as carbon, oxygen, nitrogen, or fluorine, are commonly used in PET studies.

The radioisotopes are then incorporated into another molecule (e.g., water or deoxyglucose) to form the tracer, which is then injected or inhaled by the subject. The molecule to which the radioisotope is incorporated can be a naturally occurring substance, an analogue of a naturally occurring substance or a synthetic substance (e.g., a drug). The tracer is thus composed of both labeled and unlabeled molecules.

Tracers usually have very short half-lives, so they must be used quickly, typically within one or two half-lives after their synthesis. The most commonly used tracers are 2-(18F)fluoro-2-deoxyglucose (FDG), (15O) water, (13 N) ammonia, and (15O) carbon monoxide.

## Quantification

The main advantage of PET is its ability to provide truly quantitative information about physiological processes (blood flow, glucose consumption, etc.). Each spatial unit in a PET image (a three-dimensional volume element or “voxel”) has a value corresponding to the radioactivity concentration in units of nuclear decays per second (*becquerel*) per milliliter. After correcting for physical decay, gamma ray attenuation and scatter, random coincidences, and dead-time, the radioactivity concentration in a voxel is proportional to the mass of the radioactive tracer in that voxel (Meikle and Badawi 2003).

The result is a so-called *diagnostic* PET image, reflecting the tracer’s concentration (and hence distribution/uptake) within each voxel at a certain point in time (this is also known as *static imaging*). Maps can also be obtained by correcting tracer concentration for the subject’s weight and the injected tracer dose. Although not perfect (Thie 2004), these *standardized uptake value* (SUV) maps allow comparisons between subjects,

and within the same subject over time, to be made conveniently.

On the other hand, true quantification in PET relies on what is known as *dynamic imaging*. Radioactivity concentration in a certain region at a certain time depends on the tissue’s blood flow and metabolism, as well as on the availability of the tracer to the target tissue. To calculate the former, information about the latter is required, in terms of the radioactivity concentration in arterial blood over time following the injection of the tracer. This is the *arterial input function*, which is best derived by taking several arterial blood samples from the patient and measuring plasma radioactivity at each time point.

Because this procedure is cumbersome, radioactivity concentration can instead be noninvasively derived from arterial blood within the PET image (an *image-derived input function*). However, this does not work with all tracers, is challenging when the imaged region does not include very large arteries, and only provides whole blood radioactivity concentration instead of that of plasma (Zanotti-Fregonara et al. 2011). Other alternatives include using a *reference tissue* from a region or organ where the tracer is not taken up or *modeling* the input function (i.e., deriving it from the PET image data itself).

Knowing the input function and the regional radioactivity concentration, various physiological parameters such as receptor concentration, blood flow, or glucose metabolism can be extracted using *tracer kinetic models* that mathematically describe the relationship between these factors (Bentourkia and Zaidi 2007).

## Practical Considerations

PET is quite unique in its ability, under appropriate conditions, to provide absolute quantification of many different physiological and metabolic processes. However, despite this, in most clinical and many research situations, PET is often not the first imaging modality of choice because of some notable disadvantages.

Inherent to PET is the exposure to *ionizing gamma radiation*, the extent of which depends

on the body part imaged and the tracer used. Compared to other medical imaging procedures, the amount of radiation a subject is exposed to during a PET scan is generally high, especially when combined with CT (Towson 2003). This is associated with very small increases in exposed individuals' risk of developing cancer (Brenner 2014).

Finally, not only are PET scanners very expensive to purchase and maintain (Berger et al. 2003), but the substantial costs of having an onsite cyclotron (to produce tracers with short half-lives) or of transporting longer half-life tracers from other facilities must also be taken into account. In clinical situations, particularly those in which quick decisions must be made, the benefits of accurately quantifying a disease process must be weighed against these practical drawbacks.

## Applications

The precise application of PET depends on the body part being imaged and the nature of the tracer used. PET tracers have been designed to measure blood flow, gene expression, enzyme activity, cellular metabolism, and receptor binding, finding considerable use in neurology, psychiatry, oncology, and cardiology.

### Neurology and Psychiatry

PET has opened up a myriad of opportunities for researching both normal brain function and the pathophysiology of brain diseases in living subjects. Because it permits the measurement of processes fundamentally linked to brain activity such as blood flow, oxygen consumption, and glucose metabolism, PET has been used in cognitive neuroscience to investigate the brain's functional organization (Raichle 1998). The measurement of cerebral glucose metabolism and blood flow using 18F-FDG and 15O-water, respectively, is also important for studying the pathophysiology of cerebrovascular disorders such as stroke and vascular cognitive impairment (Heiss 2014).

In addition, the communication between brain cells can be quantified and visualized using PET by measuring synaptic density (Finnema et al.

2016) as well as neurotransmitter synthesis and metabolism (Heurling et al. 2017). Pathophysiological processes, such as inflammation and blood-brain barrier disruption, that play an important role in many neurological and psychiatric illnesses can also be imaged using PET (Heurling et al. 2017).

In clinical practice, 18F-6-fluorodopa (18F-DOPA) is often used to investigate the dopaminergic system. In this way, PET helps differentiate Parkinson's disease from similar conditions (*parkinsonian syndromes*), and provides biomarkers for the progression and severity of this disease. In epilepsy, 18F-FDG PET is often used in combination with *electroencephalography* (EEG), a measure of electrical activity in the brain, to localize the focus of partial seizures, particularly when magnetic resonance imaging (MRI) shows no structural abnormalities. Increased blood flow and glucose consumption is seen within the focus during and immediately after a seizure, both of which become low between attacks. 18F-FDG PET also helps in the early diagnosis of different forms of dementia. Low glucose metabolism in the temporal and parietal lobes is characteristic of Alzheimer's disease, interestingly occurring even before symptoms of the illness begin. More specific tracers, such as 11C Pittsburgh compound-B (PIB), are capable of measuring the amount of amyloid- $\beta$  in the brain, a peptide that is closely implicated in the pathogenesis of Alzheimer's disease.

### Oncology

The vast majority of PET studies in clinical practice are done for patients with established or suspected cancer. In these patients, PET is useful for diagnosis, staging, assessing treatment response, detecting disease recurrence, and characterizing the biology of tumors.

The use of 18F-FDG, the main PET tracer used in oncology, as a general tool to detect cancer is based on the *Warburg effect*: the observation that malignant cells get their energy by taking up and metabolizing more glucose than normal cells. However, 18F-FDG is not specific to malignant cells – it accumulates wherever there is high metabolic activity, including in

infected or inflamed tissue. The main routine use of 18F–FDG PET is thus to determine the extent of the disease in patients who have already been diagnosed with malignant tumors, particularly lung cancer, colorectal cancer, lymphoma, and melanoma.

In addition, 18F–FDG PET can be used to monitor patients' responses to chemotherapy, particularly in lymphoma, breast cancer, and gastrointestinal malignancies, where reductions in the SUV of 18F–FDG can be observed after a single treatment cycle and can precede tumor shrinkage. Other PET tracers specifically target tissue hypoxia, new blood vessel formation, programmed cell death, and cellular protein synthesis (Farwell et al. 2014).

### Cardiology

In the heart, PET can be used to assess blood flow to the heart muscle (myocardium), to detect inflammation and new blood vessel formation, as well as cell death.

In clinical practice, 13 N–ammonia or 82-rubidium PET tracers are used to assess myocardial blood flow and, when combined with coronary CT angiography, how narrow the coronary vessels (the arteries supplying the heart muscle) are. Whether improperly functioning heart muscle is viable (i.e., can potentially return to normal function) can also be assessed using an 18F–FDG scan, with viable tissue showing normal tissue metabolism but low blood flow. PET is also used to determine whether atherosclerotic plaques in the coronary arteries are unstable (i.e., likely to rupture and block the artery) because increased 18F–FDG uptake is a marker of inflammation within these plaques.

Special tracers can also be used to assess sympathetic nervous system function in the heart, which is relevant to the diagnosis and prognosis of patients with heart failure. Direct imaging of markers of new blood vessel formation (angiogenesis), which occurs as a result of long-standing low blood flow to the myocardium, can be achieved using tracers targeting pro-angiogenesis factors such as vascular endothelial growth factor (VEGF).

### Hybrid Imaging

Currently, other medical imaging modalities cannot completely replace PET because they are either not truly quantitative (MRI) or have relatively limited range for measuring different processes (CT). However, both MRI and CT are better at revealing tissue anatomy due to their high spatial resolution. Because of this, PET is often combined with either CT or MRI to provide complimentary information about brain function and structure.

Combined PET/CT has the added advantage of improving the accuracy and efficiency of attenuation correction using the information about tissue density provided by CT. However, combining PET and CT has the drawback of exposing subjects to a much higher dose of potentially harmful ionizing radiation than using PET alone.

Combining PET with MRI is less risky as the latter does not produce ionizing radiation. MRI is also far better at distinguishing between different types of soft tissue than CT. However, PET/MRI is logistically complicated as it requires shielding against both radiation and the very strong magnetic field. PET/MRI scanners also have a very narrow bore (the interior part where the subject lies) because of the space occupied by the PET camera, making them uncomfortable, especially for claustrophobic or obese people. Diagnostically, PET/MRI also performs poorly compared to PET/CT in regions such as the lung (Rauscher et al. 2014), where the density of protons is low.

### Small Animal Imaging

Large animals such as pigs, dogs, and nonhuman primates can be scanned on standard clinical PET systems designed for humans. Smaller animals like rodents, on the other hand, need dedicated scanners, also known as *microPET* systems. Commercially available microPET systems have a finer spatial resolution (1–2 mm) than clinical scanners due to their smaller scintillation crystals. However, small animal PET imaging is technically challenging for several reasons, including the overall lower signal sensitivity caused by the small crystals (because fewer coincidences can be detected by each crystal), and the fact that the spatial resolution of PET is fundamentally limited

by gamma rays emitted at angles other than  $180^\circ$  (noncollinearity) causing improper localization of the point of nuclear decay (Moses 2011). However, the numerous potential applications of PET in rodent research are driving steady technological advancement, including the development of small animal scanners that allow imaging with simultaneous PET and high-field MRI (Judenhofer et al. 2008) and small, “wearable” devices for PET imaging of awake animals (Schulz et al. 2011).

## Conclusion

PET is a valuable medical imaging technique that can provide quantitative information about many different physiological processes, and the influence of diseases on them, in a relatively noninvasive manner. It has found considerable use in diagnosing and managing patients, and is also applied extensively in research on both humans and other animals. The benefits of PET in a particular context should always be weighed against its high costs and the risks of exposure to ionizing radiation.

## Pets

Mark J. Farnworth  
School of Animal, Rural and Environmental  
Sciences, Nottingham Trent University,  
Southwell, Nottinghamshire, UK

## Synonyms

[Companion animals](#)

## Definition

Pets can be defined as animals that live with humans or within human social structures where they are provided with some, or all, of their needs. They are considered to play a primarily social role within the household or community and are therefore distinct from working or production animals. Any species can be a pet, as the term is applied based on human perception of the role and value of the animal concerned, and not on an intrinsic quality of the animal per se.

## Introduction

Pet ownership appears to be culturally and historically ubiquitous (Walsh 2009), although research concerning pets in non-European cultures appears

underrepresented. It arises from the historic utility of some, but by no means all, species. However, at least in developed nations, pet ownership is now primarily for the purposes of companionship (e.g., Staats et al. 2008). Despite anecdotal evidence to the contrary (e.g., Shirley 2005), lasting and social interspecies relationships appear to be almost solely the preserve of humans. Numerous species can be sequestered into human environments and ownership with many considered to be exotic pets. Overall, pets are so common that estimates for the USA alone suggest 68% of households contain at least one nonhuman family member (American Pet Products Association 2017). Suitability of species, or sometimes breeds, as pets can be questioned based on their ability to adapt to human environments and the dangers they pose to their owners, others, or the environment (Schluppi and Fraser 2000). Readers are encouraged to consider the implications for the myriad species denoted as pets at their leisure. However, the most popular species are the domestic cat (*Felis catus*) and domestic dog (*Canis familiaris*) which, in the interests of brevity, will be the focus of this work. Current global estimates are difficult to verify with any certainty, given the wide range of lifestyles these animals may have (i.e., from entirely owned to feral). However for dogs it is suggested the population is around 1 billion (Gompper 2014) and, for cats, between 600 million and 1 billion (O'Brien et al. 2012).

Modern day cats and dogs result from the domestication of their wild ancestors: the gray wolf (*Canis lupus*) and wildcat (*Felis silvestris*). This process is estimated to have begun some 20,000–40,000 years ago (Botigué et al. 2017) and 10,000 years ago (Hu et al. 2014), respectively. Domestication is a human-mediated process, which has resulted in both morphological and behavioral changes in these species, making them more suitable for life in anthropocentric environments. How early domestication occurred is still a matter of debate. However, it is now widely considered to have resulted from two main processes. One occurs within the animal population, as individuals learned to scavenge in close proximity to people (referred to as “self-domestication”) (e.g., cats, Bradshaw 2014; dogs,

Coppinger and Coppinger 2001), and the other through selection for desirable traits by humans.

Broadly speaking domestication has functioned to reduce human-associated fearfulness and increase sociability and (in dogs) biddability. Domestication has also resulted in altered vocalizations for both dogs and cats and substantial changes in human-directed, or at least human-mediated, communication behaviors.

## Ownership

The term pet, in and of itself, remains contentious and is largely rejected in favor of the term “companion animal” in much of the literature concerned with welfare and ethics. In part, this is due to the nature of the pet-owner dyad where one individual is in possession of another. Irrespective of the treatment of a pet, it remains possible for an owner to make an entirely legal decision that is not in the animal’s interests (Wykoff 2014). This is because, legally, pets are intrinsically human property and lacking in legal agency, an occurrence that has contentiously been linked, within the animal rights literature, to ideas of slavery (Kymlicka and Donaldson 2014).

## Attachment and Relationships with Pets

### Attachment

There is little argument that most pet owners will report their relationship with their animal as loving, close, and/or familial (Crawford et al. 2006; Farnworth et al. 2012; Meehan et al. 2017) and that these bonds are built on a closeness associated with practical and emotional care, protection, and security. However, our exploration of these relationships can affect our understanding of them. There are two generally applied mechanisms, both with a range of validated tools at their disposal, but neither of which may fully explore the human-animal dynamic (see Crawford et al. 2006).

The first group assess human perceptions of the owner-pet relationship and actions toward pets; these assessments are methodologically “easier” given that they use a human self-report

mechanism. Early tools include the Pet Relationship Scale (PRS) (Lago et al. 1988) and Pet Attitude Scale (PAS) (Templer et al. 1981). More recently, the Monash Dog Owner Relationship Scale (MDORS) (Dwyer et al. 2006) and the derivative Cat-Owner Relationship Scale (CORS) (Howell et al. 2017) have been developed. The latter two, as opposed to the former, allow for the report of both positive and negative perceptions of any relationship. This makes them particularly useful for the exploration of outcomes such as relinquishment.

The second group include attempts to assess human-animal attachment by observing, or asking for recollections of, the interactions between the two parties in the dyad. This often takes the form of an adaptation of “The Ainsworth’s Strange Situation (TASS)” (Ainsworth and Wittig 1969) such as the Lexington Attachment to Pets Scale (LAPS; Johnson et al. 1992; Vanegas-Farfano and González-Ramírez 2016). Use of TASS has focused on the physiological and behavioral responses of pet dogs to separation from the owner, following introduction to an unfamiliar room containing an unfamiliar person. Both Prato-Previde et al. (2003) and Palmer and Custance (2008) identified that a dog’s behavior was indicative of “secure attachment.” This was predicated upon dogs behaving more positively toward a stranger in the owner’s presence than their absence. Similarly, dogs showed behavioral signs of attempting to reunite with the owner in the owner’s absence. Such responses may relate to the distress shown by children when separated from a parent to whom they are securely attached. These findings concur with other evidence that dogs’ heart rates and behavior are negatively affected by separation in the TASS, suggestive of emotional distress (Palestrini et al. 2005). Work applying TASS to cats is relatively sparse and those that do suggest a lack of secure attachment for cats (Potter and Mills 2015). However, behavioral studies do indicate increases in positive behaviors in cats (stretching and purring) following extended owner absences (Eriksson et al. 2017). These contrasting responses of cats and dogs to attachment-based assessments may reflect differences in the processes and purposes

of each species' domestication events (i.e., that dogs were/are primarily used for human-mediated purposes which require greater attachment).

Irrespective of the assessment tool, it is evident that the quality of the pet-owner relationship, both in terms of the human's attitudes and animal's behavior, impacts upon the experiences and outcomes for both parties within the dyad. Research using individuals' assessments of their own confidence as dog owners has been demonstrated to correlate with the attachment style, and behavior, of their dogs during use of TASS. Nonconfident owners had dogs with demonstrably weaker attachment behaviors than confident owners (Siniscalchi et al. 2013). However, contrary evidence arises in research using TASS and MDORS. Rehn et al. (2014) suggest a lack of clear associations between perceived emotional closeness and dog behavior in the TASS. Differences in dog behavior appear to result from direct owner-dog interaction styles, where owners that display more direct interaction have dogs which are less independent in their play and more proximity seeking.

### Changing Owner-Pet Relationships

The roles of pets within society are many and varied as are the relationships that exist between humans and their pets. A number of changes in owner attitudes, circumstances, and behaviors, as well as pet taxonomic grouping, affect owner-pet interactions. At the broadest level, however, there is evidence that pet owners are generally more extroverted and less fearful and report better well-being, than nonowners (McConnell et al. 2011).

When considering pet owners only, the perception of pets as "family members" was weaker in a sample of Japanese cat owners as compared to dog owners, and dogs were considered to have greater emotional capabilities (Arahoru et al. 2017). Interestingly, and with implications for causal factors, choice of pet may be influenced by fundamental aspects of the owner's personality. For example, both Reeve and Delgado (2015) and Gosling et al. (2010) found that those self-reporting as "cat people" were significantly more likely to have a

higher neuroticism and lower extraversion score as opposed to self-confessed "dog people." In turn, this may alter the expression of the owner-pet interaction, where neuroticism may be associated with the potential for greater levels of pet-directed attention. However, Vonk et al. (2016) also found no variation relative to neuroticism. Similarly, increased conscientiousness is identified as a positive pet-owner personality trait and appears not to vary relative to pet type, be that cat, dog, or "other" (Gosling et al. 2010; Reeve and Delgado 2015; Vonk et al. 2016). Whether or not women report higher levels of pet attachment than men appears equivocal; the notion is supported by Vonk et al. (2016) and (in children) Hawkins et al. (2017) but not Bagley and Gonsman (2005). The conflicting findings, even within these limited studies, suggest that an owner's personality and demographic traits have substantial, albeit complex and variable, effects on owner-pet relationships. Indeed, research suggests that, for dogs, owner characteristics have a greater effect on the relationship than dog behavior (Meyer and Forkman 2014), indicating our broadly anthropocentric attitude toward the dyad.

Attitudes toward pets have also been shown to vary relative to life events and stages. It has been proposed that the formation of bonds with pets provides children with social support and opportunities to develop nurturing behaviors (Melson 2003). Recent evidence indicates that younger children, as opposed to older children, have significantly closer bonds with cats and dogs as compared to other animals (e.g., rodents and reptiles), although the disparity is extinguished as they age (Hirschenhauser et al. 2017). Pets (cats and dogs) may provide children with opportunities for social development, increasing their quality of life above and beyond positive relationships with parents and friends (Marsa-Sambola et al. 2017); attachment may be stronger for single children as opposed to those with siblings (Hirschenhauser et al. 2017). Pet ownership may also buffer a child's perception of a stressful event (dogs: Kertes et al. 2017) and positively improve attitudes toward both humans (Paul and Serpell 1993) and other animals (Hawkins et al. 2017).

In adults, feelings of affection toward pets increase until around 54 years of age, but not thereafter (Bagley and Gonsman 2005). In a similar vein, while newly married couples and couples with adult children report strong pet attachments particularly to dogs, those with young children report a decrease in affection (Albert and Bulcroft 1988; Meyer and Forkman 2014), likely indicative of a change in the pet's relative position within the household.

### Euthanasia

As for all animals over which humans have a burden of care, there is a requirement to manage the end of life as much as its beginning. Euthanasia is a complex issue in that an owner is required to make a proxy decision about an animal's state and to weigh up future benefits against future likelihood of suffering. Such decisions are difficult to make objectively, and animals may be subjected to greater or lesser amounts of suffering based on the owner's emotional state, rather than the animal's best interests. Loss of a pet has profound impacts upon the owner akin to the grief experienced by the loss of any attachment figure (Testoni et al. 2017).

## Health Benefits of Pet Ownership

Pet ownership has been linked to a range of health benefits for the owner, or family, within which an animal resides, although such findings are equivocal. Headey (1998) indicated that increased feelings of closeness between the owner and pet resulted in a reduction in visits to the doctor and medication usage. Although this finding was based on self-reports, numerous other studies have provided links between pet ownership and benefits such as increased activity and social integration (see Cutt et al. 2007), especially for aging individuals or those with physical impairments. Following pet acquisition there is some evidence that, in the short term, the owner perceives an improvement in their health (Serpell 1991). However, reviews of the literature suggest that, although pets are important components of such effects, they are not integral to their occurrence

(e.g., a pet may only substantially improve social support where it is otherwise absent).

Improvements in cardiovascular health and postinfarction recovery have also been associated with pet ownership (Chowdhury et al. 2017; Herrald et al. 2002). This dynamic has been reviewed a number of times, focusing on a wide range of factors (e.g., Barker and Wolen 2008). Invariably these reviews conclude that, although some health benefits are evident, results should be treated with caution based on the methodologies employed and the target populations studied. By way of example, a causal link between the demographics of individual women, pet ownership, and health suggests that individuals in better circumstances, where health outcomes may already be improved, are more likely to own pets (Pachana et al. 2005).

The effects of pet ownership on the development of various diseases are likewise difficult to discern. Depending on the community an individual lives in, everyone is likely to be passively exposed to cat and dog allergens, varying in degree, but irrespective of direct cohabitation with an animal. This can make it difficult to extricate causal factors from one another. There is complex evidence as to whether cats and dogs increase or decrease the likelihood that an individual will develop asthma. However, the impacts of cats and dogs on human health are most marked for those people who are already sensitized to pet allergens or suffer from respiratory ill-health (e.g., TePas et al. 2006). Studies of human infants indicate that having a household pet significantly alters the gut biome, increasing the prevalence of *Ruminococcus* and *Oscillospira* bacteria which are, in turn, associated with a reduced incidence of allergies and obesity (Tun et al. 2017). One systematic review concludes that the incidence of asthma development for individuals born into pet-owning households is generally reduced (Lodge et al. 2012), while a wider review, including all childhood ownership studies, indicates the effect is comparatively negligible (Chen et al. 2010). It may therefore be concluded that ownership need not be predicated on a concern about child health outcomes.

## Social Facilitation

There is substantial evidence that pets can provide social support for people and that they have long been considered of similar value to other family members (e.g., Archer 1996). This social effect is of particular relevance to people who may otherwise be isolated or have experiences of social rejection (McConnell et al. 2011). Pet ownership may be particularly beneficial to numerous “at-risk” groups, including the elderly (Raina et al. 1999) and those with physical (e.g., Hart et al. 1987; Lane et al. 1998; White et al. 2017) or psychological impairments (see Beck 2005). The manner by which this occurs may be direct (e.g., the animal is the source of the interaction or companionship) or indirect (e.g., the animal promotes interaction between people).

Social facilitation primarily occurs in the public sphere and so is more likely to be associated with dog ownership. People with their dogs are more likely to interact with strangers or have conversations with others. This is because dogs act as an icebreaker for those seeking interactions, may make an owner appear more approachable, or are a focus of interest. However, the degree of interaction is influenced by the interacting humans’ genders and the breed and age of the accompanying dog (Wells 2004).

## Problems Associated with Pet Ownership

### Welfare Issues

#### Adaptation to the Human Household

Although pets have been domesticated for many thousands of years, the anthropocentric environment presents risks. Both cats and dogs have a critical socialization period (3–9 weeks and 3–14 weeks, respectively) during which exposure to people, and related objects and noises, is important to minimize undesirable responses to novel stimuli. Fear, aggression, and undesirable behaviors (such as poor litter box training in cats) are substantial contributors to erosion of the human-animal bond and substantially increase the likelihood of abandonment or

relinquishment (Salman et al. 2000; Segurson et al. 2005).

People may also misunderstand the needs, or evolutionary histories, of their animals. For example, dogs have evolved to form close social bonds with others and are further selected to bond closely with people. This can lead to the development of separation anxiety where the individual has not been habituated to being left alone for periods of time or where they are “over-bonded” with their owner (Flannigan and Dodman 2001). Likewise, although domestic cats may be considered to be semi-social, with stable aggregations forming based on resource availability (Crowell-Davis et al. 2004), they have also been selected for increased sociability as compared to their wild counterparts. Therefore, they may also suffer from separation-related issues (Schwartz 2002). Cats in multi-cat households do not appear to experience higher levels of stress than single cats as long as resource access is not limited (Ramos et al. 2013). However, for those cats which are not socialized with conspecifics, transferal of human social expectations (e.g., the need for companionship) can result in aggression between unfamiliar individuals, albeit potentially transient (Levine et al. 2005).

### Breed-Related Problems

Anthropomorphic relationships with pets (i.e., the representation of animals in human terms) may have driven selection of cat and dog breeds over time increasing phenotypic (and therefore genotypic) conformation to human expectations (Serpell 2002). These changes are potentially to the detriment of the individual animal, but are even more problematic in that they are “bred into” specific lines, making it hard to improve welfare (Universities Federation for Animal Welfare 2016). This is even more worrying given that breeds with substantial health problems, directly related to their appearance, may continue to be purchased precisely because of that appearance (Packer et al. 2017). The drive to own animals based on their appearance has been shown to be related to owner perceptions of pets as objects, property, or status markers, causing an increase in anthropocentric owner

behaviors (e.g., putting the animal in fancy dress) (Beverland et al. 2008).

Within the companion animal populations, a large proportion of dogs and a substantial but smaller percentage of cats are purebred. The demand for purebred companion animals is not a new phenomenon. However, the pressure placed on breeds to conform to social and aesthetic expectations has resulted in substantial changes to breed morphologies. In turn, the breeding for these features has had two effects: (1) the appearance of features which are exaggerated, breed-related, and in and of themselves deleterious to the individual animal (Asher et al. 2009) and (2) an increase in the prevalence of inherited disorders not related to breed standards but associated with increased homozygosity within a limited breeding pool (Summers et al. 2010).

Morphological and genetic disorders, where sublethal, may substantially reduce the longevity, or quality of life, of individuals within the associated breed (Rooney and Sargan 2010). Although the presence and effects of disorders are not uniform or ubiquitous within any one given pedigree, they are substantial enough to be considered part of the underlying nature of that breed. For example, the prevalence of von Willebrand disease has historically been substantially increased in Doberman Pinschers (and a few other breeds) (e.g., Brooks et al. 2001). Arguably this makes the disease an undesirable characteristic for that breed.

In recent years more attention has focused on brachycephalic (or short-faced) dogs (e.g., the pug and French bulldog) and, to a lesser extent, cats (e.g., Persians and exotics), in part, because they are increasing in popularity (The Kennel Club 2016; The Cat Fanciers Association 2016). This is despite substantial evidence that brachycephalism is associated with an increase in respiratory (Farnworth et al. 2016; Packer et al. 2015), dental, and ocular (Kafarnik et al. 2008) disorders. Owners of brachycephalic dog breeds appear to contribute to the problem by giving greater weight to appearance than health when choosing a breed (Packer et al. 2017) and dismissing some issues (e.g., respiratory distress) as normal breed-related behavior (Packer et al.

2012) without seeking veterinary intervention. Where confirmation-related issues are extreme, surgical interventions are often required to remedy them (e.g., Graham et al. 2017; Trostel and Frankel 2010).

Consideration of the prevalence of genetic and morphological disorders in cats and dogs has resulted in some organizations and professional bodies calling for revisions to the breed standards to promote better welfare (British Veterinary Association 2016). In some cases, there is evidence that veterinary professionals may consider specific breeds too compromised for breeding to continue (Farrow et al. 2014).

### Intensification of Breeding Practices

As with livestock, increased demand for animals drives intensification of production. Companion animals are no exception. Recent decades have seen a substantial rise in puppy and kitten “farms” or “mills” to meet the demands for purebred animals or those designated as “designer breeds” (usually first generation crosses between two pure lines). In addition to increasing the likelihood of recessive and conformational disorders being expressed (see section above), farming of pets for commercial sale can lead to poor socialization (Appleby et al. 2002) and increased behavioral problems (McMillan et al. 2013). Lack of access to the mother, or both parents, of a puppy may be a proxy measure of its origins. Absence of parents, or an inability to meet them, is likely linked to commercial breeding and has been shown to be related to increased behavioral problems (Westgarth et al. 2012). This linkage has resulted in welfare organizations promoting meeting the dam and/or sire as an important component of the purchasing process (Royal Society for the Prevention of Cruelty to Animals 2016). Despite this there is some evidence that the purchaser of popular brachycephalic breeds is less likely to meet the dam as compared to other popular purebred dogs (Packer et al. 2017). Breeding adults often experience restrictive housing environments, poor veterinary care and little hiatus between litters. They are rarely rehomed and those that are often experience

substantial behavioral and health issues related to their history (McMillan et al. 2011).

#### Nonmedical Surgical Alteration

Outside those procedures that are required to manage breed-related conditions (see above) or population (see below), there are a number of surgical procedures to which companion animals are, or have historically been, subjected. In a number of countries and jurisdictions, due to the pain and distress caused and their questionable ethicality, these procedures are no longer legal and so should be considered in light of local legislations. These surgeries are generally applied for two reasons, firstly, to minimize undesirable behaviors (where they are often promoted as a last resort) and, secondly, to improve the aesthetic appeal of an animal.

The first group of interventions include onychectomy and tenectomy in cats which are designed to prevent property damage and/or scratch injuries. The procedures, which are historically common in the USA (Patronek 2001), consist of removal of the third phalanx on each digit or, latterly, severing of the tendon that allows the claws to be unsheathed. Both procedures are considered to cause pain and discomfort, despite non-surgical alternatives being available (Cloutier et al. 2005). For dogs the most common procedures are ventriculocordecotomy or unilateral arytenoid lateralization, colloquially known as “debarking/devocalization.” As for procedures applied to cats, they cause pain and discomfort, but could be considered more invasive. Data suggest that these procedures show substantial levels of postoperative complications, including respiratory distress and pneumonia (Bahr et al. 2014). The latter group of surgical alterations, also known as surgical mutilations, include processes such as ear cropping, tail docking, and dewclaw removal in dogs.

#### Abandonment or Relinquishment

For both cats and dogs, the risks of abandonment or relinquishment are substantial. Abandonment is the act by which cats and dogs are left behind when people move or are actively excluded for the home or property of the owner. This may result in

the development of large population of free-roaming dogs and cats which are reproductively self-sustaining. Free-roaming may lead to a lack of veterinary care and increased risk of injury, human cruelty, continued reproduction, predation, or disease (see Dalla Villa et al. 2010; Finkler et al. 2011). As a result numerous lethal and nonlethal processes can be, and are, implemented to reduce the free-roaming cat and dog populations (e.g., trap-neuter-return, trap-euthanize, poisoning). Population control can be difficult based on social perceptions of control measures (e.g., Farnworth et al. 2014) and the ability to distinguish between unowned and owned free-roaming dogs and cats.

In some countries abandonment is illegal, and erstwhile owners can be prosecuted; however abandonment is only an identifiable phenomenon in countries where free-roaming populations of animals are uncommon. As a result, abandonment of dogs is likely more often identified when compared to that of cats.

Relinquishment is the process by which a cat or dog is transferred into the care of an animal organization. It may be driven by a breakdown in the human-animal bond, often as a result of behavioral problems. Another cause of relinquishment is the inability of the owner to care for the animal in question, often as a result of changing circumstances. Relinquishment may result in the animal being rehomed, although not all rehoming are successful and some result in the animal being re-relinquished. Shelters have “no-kill” policies ensuring all animals that are relinquished are maintained; however this is not the case for all organizations. Relinquishment at a shelter may be considered the better option for the animal; however it causes substantial disruption in the animal’s social bonding and reduces the amount of human-animal interaction that is possible.

#### Conflicts Associated with Pet Ownership

Although pets are commonplace within human societies, they are not universally favored. Differences in the care provided, restrictions placed upon them, and human attitudes toward pets cause numerous conflicts. This section is focused on two such examples of conflict.

## Human-Animal Conflict

### Issues of Nuisance

Dogs and cats may cause substantial public nuisance often through intrusion into the lives of nonowners. Issues identified include excessive noise from dogs barking (Juarbe-Diaz 1997) or the nocturnal activities of cats, disturbance of refuse, fecal contamination of gardens and public sites (Toukhsati et al. 2012), and disruption of traffic when free-roaming (Farnworth et al. 2012).

### Dog Bites

Legislation has been introduced into a number of countries as a result of dog bites and attacks (e.g., UK Dangerous Dogs Act 1991). This legislation is often focused on a number of breeds that are considered as predisposed to biting or aggression. Some breeds can indeed inflict substantial harm based on their size and strength, especially if the victim is a child (de Keuster et al. 2006; King et al. 2009). However, the majority of dog bites are reported to occur in developing nations (Dalla Villa et al. 2010) that appear to be inflicted on people who are familiar with the dog and, more frequently, men than women (Farnworth et al. 2012). In areas where dogs are free-roaming, the likelihood of being bitten appears to rise.

### Zoonotic Diseases and Parasites

Dogs and cats both carry diseases that are zoonotic, (i.e., those that can be passed from the animal to people). These diseases include the following:

Cats: Ringworm infection, toxoplasmosis, salmonellosis, campylobacteriosis, giardiasis, cryptosporidiosis, roundworm and hookworm infection, cat scratch disease, and rabies

Dogs: Ringworm infection, salmonellosis, leptospirosis, Lyme disease, campylobacteriosis, giardiasis, cryptosporidiosis, roundworm and hookworm infection, and rabies

The risk that most zoonotic diseases carry is relatively low, although the larger the population the greater the risks of transmission (Katagiri and Oliveira-Sequeira 2008; Parrado et al. 2011), and

they are most likely to cause harm to people who are already immunologically compromised or naive. One major exception is rabies, where global eradication attempts are already underway (see Morters et al. 2013).

### Animal-Wildlife Conflict

Both dogs and cats cause, or are perceived to cause, substantial predatory (Loss et al. 2013) or competitive (Butler and Toit 2002) impacts upon local wildlife. Dogs may also cause nuisance or harm to domestic livestock. These impacts may be particularly marked when they represent introduced mammals to which endemic species are poorly adapted (e.g., Nogales et al. 2004; Berger et al. 2007). To this end, the domestic cat has been considered one of the most problematic introduced predators, something which is exacerbated by their ability to free-roam. Resolution of the issue of pet-wildlife conflict is complex, directly as a result of the close ties local communities may have with their animals (e.g., Hughes and MacDonald 2013; Loyd and Hernandez 2012).

The literature around these problems is not complete, and it remains unclear as to whether cats and dogs may benefit some native species by controlling other invasive predators (e.g., rats). The impacts of urban pets are also less well understood (see Kikillus et al. 2017; Hughes and MacDonald 2013) than the impacts of feral dogs and cats (i.e., those living outside human control or human environments), leading to a requirement for more systematic exploration of anthropogenic problems arising from pet ownership.

## Conclusion

Pets perform myriad roles within human societies, both providing and deriving substantial benefit. However, the relationship is not one of equal standing for both parties, which results in a number of areas of concern. Improved knowledge about the relationships between owners and their pets, the needs of pets, as well as more focused legislation for their management may be highly beneficial.

## Pharmacogenetics

Kanza Khan

Department of Psychology, University of  
Southern Mississippi, Hattiesburg, MS, USA

## Synonyms

Personalized medicine

## Definition

The branch of research that examines how an individual's genetic code will affect their reaction to drugs.

## Introduction

The field of pharmacogenetics is concerned with improving patient outcomes and response to drug treatment(s). To this end, research efforts in this field have many aims: to identify genetic variants that alter an individual's response to pharmacological agents, to determine the population frequency of identified polymorphisms, and to search for safer or more effective treatments/doses. The ultimate goal of pharmacogenetics is to predict a patient's response to a treatment based on genetic differences, thereby improving success and reducing adverse outcomes (Spear et al. 2001).

Currently available pharmaceutical drugs must go through extensive testing to establish their efficacy in improving outcomes while also minimizing mild or severe adverse outcomes. Despite such testing, there remains a great level of variability in drug responses. These inter-person differences may arise from controllable (e.g., mis-dosing or drug-drug interactions) or uncontrollable (e.g., allelic mutations) factors. The field of pharmacogenetics is most interested in the differences that result from uncontrollable factors, i.e., genetic predispositions.

The genetic code is a highly complex set of rules which regulates the transcription and

translation of genetic material (RNA and DNA) into proteins that, for instance, regulate drug metabolism, absorption, and excretion. Naturally occurring mutations in DNA may alter the composition and structure of proteins and enzymes, ultimately altering drug metabolism and risk of adverse outcomes (e.g., toxicity; Sissung et al. 2014).

## Pharmacogenetics of Membrane Transporters

Membrane transporters are large transmembrane proteins that span the phospholipid bilayer and facilitate the transport of ions, small molecules, drugs, and substrates against their gradient. Humans express many types of membrane transporters; these differ in their direction of molecular transport (influx or efflux), location in the body, and mechanism of action. The ATP-binding cassette (ABC) transporters are a superfamily of efflux proteins that generally draw substrates out of tissues and into the systemic circulation, eventually promoting the clearance of drugs. To date, 49 ABC genes have been identified. The *ABCB1* transporter is commonly found in normal cells of the adrenal gland, kidney, liver, colon, jejunum, pancreas, and in the capillary endothelial cells in the testis and the blood brain barrier (Fung and Gottesman 2009). A total of 66 single-nucleotide polymorphisms (SNP) have been identified in the *ABCB1* gene (24 synonymous, 42 non-synonymous). Some of these SNPs have been implicated in altered mRNA transcription, protein folding, and drug pharmacokinetics. In humans, the functional consequences of polymorphisms have not been fully elucidated; to date, the SNPs that have been studied in vitro have not produced clinically significant effects on protein function (Fung and Gottesman 2009).

Influx transporters mediate the cellular uptake and reabsorption of drugs against a concentration gradient. These membrane proteins also span multiple domains and assume complex structures that allow for the transport of substrates into, and sometimes out of, the cell. Common influx proteins are the organic anion transporters (OATs and OATPs),

organic cation transporters (OCTs), and oligopeptide transporters (PEPTs). Influx proteins are also polymorphic, with some allelic variants affecting drug efficacy and toxicity. One of the more commonly studied influx proteins, the OATP1B1 protein, is a hepatic influx transporter (Niemi et al. 2011) with an identified total 41 non-synonymous SNPs, to date. These polymorphisms are associated with structural and functional changes in the transmembrane protein, some of which have serious implications in the clinical setting. Studies evaluating the pharmacokinetics of *SLCO1B1* (coding for OATP1B1) gene variants have found different clearing rates for pravastatin, a statin that is used to reduce serum LDL levels. Certain allelic variants (*SLCO1B1\*1B*) are associated with a low clearing rate of the drug, which can be associated with a risk of statin-induced myopathy (Pasanen et al. 2006). Fortunately, the targets of the allelic variant are substrate specific; similar statin-reducing drugs (e.g., rosuvastatin) have unaltered pharmacokinetics in individuals with the *SLCO1B1\*1B* allelic variant (Choi et al. 2008).

### Drug Responses: Efficacy and Adverse Outcomes

Aside from the rate of influx into or efflux from a cell, there are several other genetic factors that determine the efficacy or risk of adverse outcomes. Among these are the metabolizing enzymes and drug targets. A prominent example of such effects is highlighted in the variability in dosing guidelines and responses to the commonly prescribed anticoagulant warfarin. Once prescribed, patients are required to visit with the practitioner frequently to ensure that the dose prescribed is safe to use; underdosing and overdosing have serious risks. Patient factors (e.g., age, weight, sex) can account for roughly 20% of warfarin dose variability, and genetic variation accounts for the remaining variability (Gladding et al. 2010). Candidate association studies have found two candidate genes responsible for the differences in dosing: *CYP2C9* and *VKORC1*, coding for the enzyme cytochrome P450 2C9 (metabolizes S-warfarin), and vitamin K epoxide

reductase (warfarin's target), respectively (Limdi et al. 2010). Allelic variation in both of these genes leads to wide differences in dosing guidelines; depending on the type of variant of one or both genes, the individual may be prescribed as low as 3.3 mg/day or as high as 6 mg/day. Because of the high level of variability, pharmacogenetic-guided dosing tools for warfarin administration are now available (<http://www.warfarindosing.org>).

Allelic variations in genes that are not directly involved in the transport or metabolism of a drug may also affect responses to treatment. Several instances of this phenomenon have been documented in, for instance, the risk for deep vein or cerebral vein thrombosis in women taking oral contraceptives or the development of cardiac arrhythmia in patients receiving clarithromycin (antibacterial, antiulcer medication). While adverse drug outcomes such as these are typically noted in the list of potential side effects of a drug treatment, the risk for developing an adverse drug response is highly dependent on genetic factors.

Though not widely studied, the developmental stage also plays an important role. Some metabolic proteins have differential expression depending on stage of development. For example, CYP2E1 (a member of the P 450 family) plays a role in metabolizing xenobiotics. Expression of this enzyme during the third trimester is only 10% of the expression in infants older than 90 days (Krasniak et al. 2014). Further, owing to the differential expression of metabolizing proteins, young children chronically treated with acetaminophen have high rates of hepatotoxicity relative to older children and adults (Krasniak et al. 2014). Unfortunately, the mechanism of action is not fully understood. As such, neonates and young children have different clearance levels of xenobiotics and other drugs, which must be taken into consideration when determining proper dose.

### Pharmacogenetics in the Laboratory

The field of pharmacogenetics originated in the 1950s from observations that genetic differences affected rates of drug clearance (i.e., substrate

levels in plasma and/or urea) and response to treatments (e.g., adverse outcomes, high metabolism). Since then, the systematic study of genetics' role in the physiological response to a pharmacological agent has grown tremendously, with efforts in genomic, transgenic animal models, and in vitro research expanding our ability to diagnose allelic variations and administer safe and effective doses.

A common method to identify candidate genes is through a case-control study. In such studies, patients who have positive reactions to a drug regimen are recruited to a control group, and individuals presenting with either no reaction or an adverse reaction to the drug are recruited to the case group. Then, the researcher looks for genetic variation that may account for the differences in reaction among participants. Though the study of polymorphisms and drug transport/metabolism kinetics are best studied in vivo, it is not always ethical or feasible to conduct such evaluations. Animal models and in vitro studies, then, are an appealing approach. In many cases, it is possible to develop a genetic model or a cell line of a human polymorphism.

In animal models, the researcher can recreate the human phenotype through gene deletion, allelic overexpression, knock-in/-down models, transgenic models, and more. This type of study has the advantage of allowing the researcher to study the effects of the genetic polymorphism on protein formation and function in a controlled setting. Furthermore, animal models also circumvent some of the problems associated with human clinical trials (e.g., requiring large sample sizes) or in vitro studies. In vitro studies are useful when an animal model is not readily available. In an in vitro study, model cells are transfected with cDNAs that represent the polymorph or wild-type gene. While this type of study provides data on the transport kinetics of a drug, it cannot provide a detailed overview of the metabolism or the potential for other adverse drug effects.

While animal models and in vitro studies may paint an incomplete picture of the pharmacogenetics, they may provide additional information that can be used for in vivo studies or inform drug dosing guidelines. As a result of all of the research efforts (animal models, in vitro, and clinical

studies), there have been tremendous advances and discoveries of the genetic associations with drug responses. This has spurred the clinical implementation of pharmacogenetics, wherein the patient is genotyped to determine the likelihood of an adverse reaction or determine sensitivity to treatment. The broadening list of known genetic markers' effects on drug response has also resulted in genetic labeling on new drugs, as well as updating product labels for many existing therapies (e.g., warfarin). Practices such as these allow the clinician to more accurately and safely prescribe a treatment to their patient.

## Synonyms

Behavioral qualities; Genotype; Physiological appearance; Visible characteristics

## Definition

Phenotype is attribute or observable appearances/characteristic of an individual organism demonstrating its distinctive morphological, developmental, physiological, biochemical, or behavioral assets.

## Introduction

All the visible characteristics of an organism arise by genotype interaction (complete genetic inheritance) and the impact of environmental aspects. Examples of visible or observable characteristics

comprise color, shape, size, behavior, and biochemical properties. When used to describe a human, this set would contain body weight, hair length, or behavioral qualities such as nervousness (<https://www.investopedia.com/terms/p/phenotype.asp#ixzz5Ty7FsfDM>). In the early twentieth century, Danish botanist and geneticist Wilhelm Ludvig Johannsen introduced the word phenotype to describe the visible and measurable individualities of organisms (he also introduced the word genotype, in reference to the hereditary units of organisms). When two or more conspicuously diverse phenotypes exist in the similar population of a species, the species is called polymorphic. A well-documented example of polymorphism is Labrador Retriever coloring; although the coat color depends on several genes, it is perceptibly seen in the environment as brown, yellow, and black color.

An individual's phenotype may change continuously through their entire life due to changes in environmental conditions and the morphological and physiological changes related with aging. Miscellaneous environments can affect the growth and development of inherited traits (e.g., size is affected by availability of food supply) and alter the expression by identical genotypes (e.g., twins maturing in different families). In nature, the impact of the environment forms the basis of natural selection, which primarily works on individuals, preferring the survival of those individual organisms with phenotypes best suited to their current environments. The existence improvement convened to individuals exhibiting such phenotypes allows those individuals to reproduce with comparatively high degrees of success and thus pass on the efficacious genotypes to next generations (<https://www.investopedia.com/terms/p/phenotype.asp#ixzz5Ty7FsfDM>).

The abilities that contribute to phenotype arise from a combination of congenital genetic traits (genotype) and external or environmental dynamics. However, frontiers between genotype and phenotype are remarkably complex, for instance, all hereditary possibilities in the genotype are not expressed in the phenotype, because certain are the consequence of recessive, latent, or inhibited genes (<https://www.britannica.com/science/phenotype>).

## Phenotypic Variation

Phenotypic variation (due to pivotal inherited genetic change) is an essential requirement for evolution by natural selection. Natural selection interrupts the genetic organization of a population indirectly through the contribution of phenotypes. In natural selection, evolution would be not possible without phenotypic variation (Lewontin 1970).

The communication between genotype and phenotype has been hypothesized by the subsequent relationship:

Genotype (G) + Environment (E) → Phenotype (P)

A more apparent kind of the relationship is:

Genotype (G) + Environment (E) + Genotype  
and Environment Interactions (GE)  
→ Phenotype (P)

Genotypes frequently have ample flexibility in the modification and appearance of phenotypes; in several organisms these phenotypes are very diverse under variable environmental conditions (ecophenotypic variation). For example, the plant *Hieracium umbellatum* is established in two opposite habitats in Sweden. One habitat is rocky, seaside cliffs, where the plants are bushy with broad leaves and prolonged inflorescences; the other is amid sand banks where plants grow prostrate with narrow leaves and dense inflorescences. These habitats alternate along the coast of Sweden and the habitat that the seeds of *Hieracium umbellatum* land in determine the phenotype that grows (Bergfeld et al. 2009). The plants possess their habitat-specific appearance under standardized experimental conditions. An example of arbitrary variation in *Drosophila* flies is the quantity of ommatidia, which may fluctuate (randomly) amid left and right eyes in a single individual as much as they do between altered genotypes overall or between clones raised in miscellaneous environments (Dolph et al. 2011). Another example is *Donax variabilis* shell pattern. The outside of the small shell of this species can have any one of a wide range of possible

colors, from almost white, through yellow, orange, red, purple, pink, to brownish and blueish, with or without the presence of darker rays (<https://www.revolvvy.com/page/Donax-variabilis>; Rosenberg 2009; iLoveShelling 2014; Fig. 1). The notion of phenotype can be extended to variations beneath the level of the gene that disturb an organism's fitness.

## The Extended Phenotype

Extended phenotype term pronounced by Richard Dawkins. According to Dawkins, a phenotype comprised all response that a gene has on its environments/surroundings, involving other organisms known as an extended phenotype (Dawkins 1978). For example, an organism such as a persist amends its environment by constructing a beaver barrier; this can be contemplated an expression of its genes, such as incisor teeth which uses to alter its environment. Likewise, while a bird feeds a breed parasite, e.g., a cuckoo, it is accidentally spreading its phenotype; and when genes in an orchid interrupt orchid bee behavior to enhance pollination, or genes in a peacock disturbing copulatory verdicts of peahens, once more, the phenotype is being extended. Another example, in the caddis' salivary gland, the caddis house constructed by a silk which is wrapped to prevent against predators and boost the mate selection. According to Dawkins's view, genes are designated by their phenotypic effects (Dawkins 1982). Many of the scientists generally support that extended phenotype concept is significant; however its role is regularly illustrative, instead of supporting in the strategy of experimental tests (Hunter 2009).

## Phenotypic Adaption

Evolutionary adaptations to new environments commonly reverse plastic phenotypic changes. In a new environment, phenotypic adaptation can consist of two phases: plastic change and genetic change (Fig. 2a). In the first phase, the

**Phenotype, Fig. 1** Various coloration and phenotypes pattern in a species of small edible saltwater clam *Donax variabilis* (Coquina)

environmental shift activates phenotypic changes without mutation; such types of changes are recognized to as plastic changes (PCs) regardless of their fitness effects. In the second phase, phenotypes are changed by mutations that accrue during adaptive evolution. Although, most of the previous evolutionary studies concentrated on the second phase, but present years have stated a progression in the dispute for the significance of the first phase in adaptation (Laland et al. 2014, 2015; Levis and Pfennig 2016). It is proposed that the plastic phenotypic alterations are frequently required for organism existence in a new environment, which is compulsory because adaptive evolution is not possible, if the environmental adaptation destroys all individuals (Robinson and Dukas 1999). Moreover, it is recommended that genetic adaptations in the second phase are alleviated by the PCs in the first phase (Laland et al. 2014, 2015). For instance, plasticity can change the phenotypic value of an organism closer to the adapted state in the new environment

and provide as a stepping stone to adaptation (Price et al. 2003; Fig. 2b).

For a trait, the plastic phenotypic variation influenced by an environmental shift and the successive genetic change (GC) during the adaptation to the new environment could be in the similar direction toward the ideal phenotypic value in the new environment. Figure 2b indicates that the PC is reinforced by the adaptive GC and thus is deliberated adaptive (Ghalambor et al. 2007, 2015). The PC and the subsequent GC could also be in reverse directions. Figure 2c shows that the PC is reversed by the adaptive GC and is hence usually considered nonadaptive (Ghalambor et al. 2007, 2015; Ho and Zhang 2018).

### Phenotype Matching

Phenotype matching is essential to allow variance of behavior toward earlier unmet animals.

**Phenotype, Fig. 2** Gene expression changes in experimental evolution. (a) Phenotypic adaptation is considered by comprising the phenotypic standards of a trait at three stages: ancestral organisms adapted to the primitive environment controlled in the primitive environment (stage o); ancestral organisms measured in the new environment (stage p); and developed organisms adapted to the new environment distinguished in the new environment (stage a). Plastic alterations refer to alterations from stage o to p,

while genetic alterations refer to alterations from stage p to a. (b) When a pair of plastic and genetic phenotypic alterations of a trait, both are larger than a predetermined cutoff and are in the similar (same) direction known as reinforcing. (c) When a pair of plastic and genetic phenotypic alterations of a trait, both are larger than a predetermined cutoff and are in the dissimilar (opposite) direction known as reversing

Because phenotypic matching almost continuously employs information accomplished from relatives for inequity, these behavioral verdicts are stable with kin selection. Frequently, in phenotype matching the used phenotypes are known as cues, instead of signals. An animal making a more cognitive conclusion links the cues available by the other animal with an internal expectation of what virtual appearances/odors/sounds resemble. This internal expectation is termed a template (Breed 2010).

Phenotype matching is the capability to fascinate the phenotypes of neighboring animals and to expenditure that information to categorize earlier unmet animals. The distinctive arrangement is for phenotypic learning to occur initially in development, when the nearby animals are littermates and parents. On a functional level, this type of phenotype matching is known as kin recognition (Breed 2010).

## Behavioral Genetics and Behavior as a Quantitative Trait

There are numerous behaviors which differ in response to the environmental factors, such as biotic or abiotic, and thus accomplish a significant form of phenotypic plasticity. Behavioral genetics is the inferences amid genetic variances between animals and behavioral changes. Changes among families, subspecies, and species altogether aid to specify how ample variables role genes have in behavior (Renn and Schumer 2013). Behavioral plasticity, similar to more plastic characters, can derive via genetic assimilation or accommodation. The nature of changes in gene expression plasticity that associate with these evolutionary modifications in phenotypic plasticity (Pfennig et al. 2010; Renn and Schumer 2013). The change in gene manifestation level caused by first-order phenotype triggers ample behavioral variation

(Snell-Rood 2013). A number of studies have stated that the genes which show variation in their expression associated with the flexible and developed modifications in behaviour (Snell-Rood 2013).

Animal behavior phenotype is determined by an association of environmental and genetic factors; scientists can evaluate genetic influences by protecting animals in a common environment. For instance, testing to see if variances amid subspecies from diverse environments persist when they are kept together allows comparison of genetic and environmental effects on behavior. Many phenotypes or traits differ constantly, instead of having discrete forms. For example, height in humans, average adult humans range in height over a length of more than 2 ft (more than half a meter). Generally, quantitative traits are typically distributed like in a bell-shaped curve. Behavioral phenotypes frequently differ in this mode. This is mostly accurate of phenotypes for activity levels. Honey bee colony pollen selection rates serve as a typical example of behavioral phenotypes (Johnson and Tsutsui 2011). A normally distributed trait, whether it is physical (height) or behavioral (pollen collection), is normally the result of the involvement of several genes.

## Summary

Phenotypic variations are caused with the result of environmental factors on the expression of genetic potentials. Phenotypic changes do not comprise any inherited variations and are not transferred to upcoming generations; thus, they are not considerable in the progression of evolution. Furthermore, phenotypic changes comprise phases in an organism's life cycle and seasonal changes in an individual.

## Phenotype Matching

Jill M. Mateo

Department of Comparative Human  
Development, The University of Chicago,  
Chicago, IL, USA

W. D. Hamilton's concept of inclusive fitness is arguably the most significant refinement of Darwin's theory of natural selection, explaining the evolution of costly behaviors that are directed toward close kin (Hamilton 1964). Hamilton also predicted the evolution of mechanisms to facilitate the accurate recognition of kin. Two common mechanisms of kin recognition are familiarity and phenotype matching. With familiarity (also known as "prior association"), animals learn the

cues or labels of related individuals during early development (e.g., siblings) and later discriminate these familiar individuals from unfamiliar ones. Phenotype matching is an extension of familiarity. Here, animals learn their own phenotypes and/or those of their familiar kin and later compare or match the phenotypes of unknown animals to this learned recognition template. For phenotype matching to occur, there must be a correlation between phenotypic and genotypic similarity, so that individuals with traits that most closely match an animal's template are its closest kin. Both mechanisms involve a comparison between templates and unfamiliar or familiar phenotypes, but familiarity leads to recognition only of previously encountered familiar individuals, whereas phenotype matching permits discrimination among various classes of unfamiliar kin and nonkin. That is, unfamiliar kin are "recognized" as belonging to a particular kin class. This recognition occurs through generalization from recognition templates, with the degree of match between an encountered phenotype and an individual's template indicating the degree of genetic relatedness between the two animals (Holmes and Sherman 1982).

Selection will favor the evolution of kin recognition via phenotype matching when novel kin are encountered for the first time after early development because it allows discrimination among individuals without prior association, by comparing strangers' cues to a learned recognition template. This mechanism would be expected in several socio-ecological contexts. These include but are not limited to systems that have multiple mating by males (for recognition of paternal half-siblings), natal or breeding dispersal (for males to recognize their older brothers or fathers), communal nesting (for females to discriminate between related and unrelated young which are both familiar), no parental care (to avoid inbreeding hazards), and overlap of generations, particularly in long-lived species. Phenotype matching would also be favored in cases of intra- or interspecific parasitism (Holmes and Sherman 1982; Mateo 2004).

Self-referent phenotype matching is when animals learn and use their own phenotypes as

referents for kin recognition (dubbed the “armpit effect” by Richard Dawkins in 1982). Self-matching provides the most accurate assessment of relatedness, as an animal’s own cues better reflect its genotype than those of its close kin. That is, an animal’s coefficient of relationship to itself is 1.0, whereas its coefficient of relationship to its nearest kin such as parent, offspring, or full sibling is 0.5. Self-matching would be favored in species with multiple maternity or paternity to discriminate among full and half-siblings or when individuals are likely to encounter older (or younger) siblings after natal dispersal. It would also be favored when there is a risk of learning referents from nonkin such as in communal nesting or brood-parasitic situations. Animals would then not have to learn the cues of familiar (but unrelated) individuals but instead could rely solely or largely on its own cues. Similarly, self-referent phenotype matching would be especially useful in nepotistic situations, when animals need to identify their closest kin, whereas in mate-choice contexts using other referents such as parents and siblings would be sufficient to avoid close inbreeding (Mateo 2004).

Kin-discrimination abilities via phenotype matching have been demonstrated in many taxa, including birds, rodents, primates (including humans), anurans, fish, and insects (Beecher 1988; Mateo 2003; Waldman 1991). Most studies have examined kin labels in the olfactory modality, but others have considered facial and acoustic cues. Cross-fostering, isolation, and natural experiments of animals separated from kin have been used to determine if animals can use phenotype-matching abilities to recognize kin (Mateo and Holmes 2004). However, few studies have examined the context(s) in which such abilities are used (e.g., mate choice, nepotism, nest or offspring identification in a colony, etc.).

## Definition

Property of a genotype to generate different phenotypes in response to the environment.

## Introduction

All observable characters of an organism are called ► [phenotype](#), comprising behavioral,

morphological, or physiological traits. Each phenotype is determined by information contained in the DNA – or ► **genotype** – in concert with environmental inputs. Environmentally induced changes in the phenotype, without genotypic variation, are denominated phenotypic plasticity. Although trait variation is a response to environmental cues, plasticity's sensitivity and direction of expression are determined genetically. As phenotypic plasticity exhibits a genetic component, it is under natural selection and can evolve.

The range of all possible phenotypes across an environmental gradient produced by a single genotype is described mathematically by a reaction norm (or ► **norm of reaction**). The specific genotype response to changes in the environment is a result of the genotype-environment interaction, which corresponds to the slope of the reaction norm. A slope different from zero indicates phenotypic plasticity. Parallel curves that differ only in their height demonstrate differences in the trait mean value, but not in plasticity. These two aspects of reaction norms, plasticity (slope) and trait mean value, might be or not interrelated depending on the molecular mechanisms of control of trait expressions. Another important feature of a reaction norm is that it is trait-specific. Organisms are a mosaic of nonplastic and plastic traits, as well as different forms of plasticity.

Plasticity can also be visualized graphically through performance curves. Performance curves show how biological processes (e.g., growth and development rate) vary in response to an environmental variable (Huey and Stevenson 1979). In contrast to reaction norms, performance curves are a property of the individual as a whole, not of the genotype.

Phenotypic variation can be continuous or discrete. The most common form of discrete variation is polyphenisms. Polyphenism is when a genotype produces two or more alternate phenotypes in response to a determined environmental cue, for example, environmental sex determination in fishes and reptiles. In this case of discrete

variation, the reaction norm is both plastic and canalized because it generates a single phenotype in a set of environments. ► **Canalization** is a property of the developmental systems that restricts phenotypic variation, enabling the production of the same phenotype, despite changes in environmental conditions. As canalization limits phenotypic variation, it has been often seen in opposition to plasticity; however, they are not mutually exclusive. Homeostasis (i.e., measure of the resilience of developmental systems to environmental changes) is a possible consequence of canalization, and it is negatively related to plasticity.

Phenotypic plasticity is an inevitable outcome when physicochemical processes are disturbed (i.e., breakdown of the homeostasis) during development in stressful conditions. Therefore, organisms are inherently plastic in the absence of buffering mechanisms. Most of these plastic responses to stress will probably be maladaptive. However, some developmental variants might increase chances of survival and reproductive success and fitness.

Phenotypic plasticity is a possible solution for the problem of adaptation to habitats with fluctuating conditions in which selection favors distinct phenotypes in each one. In such instances, plasticity is adaptive, and there might be evolutionary changes in the trait's sensitivity to environmental stimuli. Once plasticity evolves as an adaptation, it can persist in organisms in a latent state under homogenous conditions if there are no costs to its maintenance.

In stressful circumstances, plasticity can generate an explosion of novel phenotypic forms either by the breakdown of homeostasis or by hidden plastic responses resulting from past evolutionary processes. Thus, genetic variations that usually have little or no effect in phenotypic variation (i.e., cryptic genetic variation) are revealed, providing the raw material for natural selection to act.

West-Eberhard (2003) proposed the plasticity-first hypothesis in which she describes a sequence of events by which developmental

**Phenotypic Plasticity, Fig. 1** Evolution of phenotypic plasticity and its role in evolution. (a) Lineage 1 generates only one phenotype during normal development, which corresponds to the ancestral state of the clade; lineage 2, in contrast, produces different phenotypes in response to environmental cues; this phenotypic plasticity is an adaptation to this species habitat; lineage 3 produces a phenotype similar to the environmentally induced phenotype observed in lineage 2. (b) When exposed to novel

environmental conditions, a diverse set of phenotypes are produced in lineage 1 – representing cryptic genetic variation. Most of these novel phenotypes are maladaptive; one (solid purple line), however, is advantageous in the novel environment; the reaction norm responsible for generating the adaptive novel phenotype has been selected and evolved as adaptive phenotypic plasticity in lineage 2; differently, in lineage 3 occurs the genetic assimilation, such that the novel phenotype becomes canalized

plasticity can lead to genetic evolutionary change (Fig. 1). As explained above, when exposed to novel environments, plasticity can generate by chance phenotypes close to the optimal value favored by selection. If there is genetic variability for the form by which individuals produce such variants, selection can refine the trait by altering the regulation of its expression – causing genetic accommodation. In the absence of selective pressures for the maintenance of plasticity, there can be a reduction of the trait's sensitivity to the environmental cue, leading to its constitutive expression – causing genetic assimilation.

Phenotypic plasticity can produce, as well, phenotypes that are in the same direction favored by selection, but with lower values than the optimum. If so, plasticity might enable populations' survival and establishment in the novel environment, allowing natural selection to act in the pre-existing genetic variation or new mutations to arise. Hence, plasticity would act facilitating the movement from one adaptive peak to the other (Price et al. 2003).

## Conceptual History of the Term

The term plasticity was coined by Nilsson-Ehle in 1914 to describe environmental effects on the phenotype, although some studies describing phenotypic variation as the result of environmental changes precede the term. Woltereck (1909), in a seminal study, described mathematically the phenotypic variation in the small crustaceans of the genus *Daphnia*. Woltereck conceived the term of reaction norm, which he suggested as being hereditary. However, the idea of interaction between genotype and environment was not clear at this time. Johannsen (1911), in turn, distinguishes the concepts of phenotype and genotype, demonstrating that even in homozygous lineages with genetic control, he still observed phenotypic variation due to environmental influences.

In 1949, Schmalhausen brought the neo-Darwinian perspective to the conceptualization of the evolution of phenotypic plasticity. According to him, the evolution of a phenotype is mediated by two factors, the external and

internal environments, existing two types of environmentally dependent development: the morphosis, which is nonadaptive, and the dependent autoregulatory morphogenesis, which is adaptive. A few years later, Bradshaw (1965) proposes that plasticity is an alternative mechanism of adaptation of organisms to changes in environmental conditions, counter to the view of most evolutionary biologists at the time, who thought plasticity was a source of error during the ontogenetic development and which should be minimized. From the second half of the twentieth century, plasticity studies have become more recurrent, improving its comprehension. In 2003, West-Eberhard compiled and updated a few concepts and terminologies that had been proposed by other researchers over the previous century. Since then, numerous works have been demonstrating that plasticity has a crucial role in evolution and is a key point in the extended evolutionary synthesis (or ► [modern synthesis](#)).

### Examples of Phenotypic Plasticity

Some works show that phenotypic plasticity can be a mechanism responsible for variations in animal behavior in response to climate changes. A study by Charmantier et al. (2008) done with great tit birds of the species *Parus major* in the United Kingdom demonstrated that the mean egg-laying date advanced by about 14 days in the last 47 years. Their data indicate a relationship between the mean egg-laying date and the environmental temperature over the years, occurring a markedly linear increase in pre-laying temperature since 1970. Concomitantly, there has been a shift in a similar fashion of larval biomass of winter moth larvae, a key food resource for their rapidly growing offspring. Selection thereby favored birds that procreated in time to the peak of food availability, synchronizing birds' egg-laying dates with the timing of caterpillar emergence over the years. The rate of phenotypic changes was too rapid to be explained by

natural selection being more likely the result of individual adaptive plasticity.

Many animal species show considerable geographic variation in body size. Changes in body size can occur due to genetic modifications – possibly through evolutionary adaptation – or by effects of food availability, the latter being, for example, the case of the grass snake, *Natrix natrix*. Madsen and Shine (1993) observed for six years the patterns of body growth of island and continental populations of the grass snake. They found that female grass snakes from the island have smaller body sizes than those from the continent and that the diet of the former is composed of smaller preys. Next, they performed an experiment to test if difference in body size between populations was an effect of distinct food resources. Snakes collected from both populations were raised in captivity with equal food supply and were measured at the same time during the years. Analyses showed that the growth pattern of snakes from different populations did not differ when raised in the same conditions. This suggests that the differences observed between insular and continental snakes are a direct result of influences of food availability in body growth, without any genetic change. Besides, the similar response of the snakes to the treatments indicates that both populations share the same reaction norm.

A specific case of phenotypic plasticity is polyphenism, which can be illustrated by behavioral shifts in the species of locust *Schistocerca gregaria* (Pocco et al. 2019). This locust exhibits two forms according to the population density: a solitary phase with green coloration and a gregarious phase with black spots. This study demonstrates that nymphs living agglomerated are more active and more attracted by conspecifics. Body size is also greatly influenced by population density, with gregarious females being smaller than isolated females, in contrast to males, which are smaller in the isolated phase. These observations show, once again, that besides environmental factors, population density can alter significantly morphology, behavior, metabolism, and reproduction throughout animals' life history.

## Introduction

In 1959 the chemist Adolf Butenandt and his team identified the first pheromone – the silk moth’s sex pheromone bombykol (Butenandt et al. 1959). This discovery prompted the creation of the word “pheromone” (from the Greek: *pherein*, to carry or transfer, and *hormón*, to excite or stimulate) (Karlson and Lüscher 1959). Butenandt’s discovery (1959) also established that chemical signals between animals exist and can be identified by researchers.

From the outset, Karlson and Lüscher (1959) anticipated that pheromones would be found across the animal kingdom, from insects and crustaceans to fishes and mammals. Actually it is likely that the majority of species across the animal kingdom use pheromones for various kinds of communication in every habitat on land and underwater (Wyatt 2014). To date, only insects, fishes, and mammals have been studied in any depth, while little is known about the pheromones of other taxa.

However, the idea of chemical communication was not new in 1959. For example, the ancient Greeks knew that the secretions of a female dog

attracted males; Charles Darwin included chemical signals as outcomes of sexual selection, describing the strong smells of breeding males in moths, pythons, crocodiles, musk ducks, goats, and elephants; and many scientists in the nineteenth and twentieth centuries, including Niko Tinbergen, had worked on phenomena that we would recognize as involving pheromones (reviewed by Wyatt 2014). However, since the amounts emitted by an individual animal were very small, these scientists could not easily identify the pheromones due to the limitations of the techniques available at that time. Butenandt had the novel idea of using domesticated silk moths, which could be reared in the quantities necessary to collect enough material for analysis using the chemistry of the 1950s.

Since 1959 a great variety of organic molecules has been identified as pheromones (reviewed by Wyatt 2017). This reflects the diversity of the animal kingdom and offers an ongoing challenge for scientists interested in the identification, synthesis, and exploration of natural functions of novel compounds.

## What Are Pheromones? Types and Functions of Pheromones

Pheromones are chemical substances generated by an individual that can affect another individual. The sensing individual will answer by using responses varying from alarm reactions to sexual behavior and to specific types of behavior in lower forms. Pheromones have been very well documented for insects but pheromone compounds vary considerably from species to species.

Pheromones are molecules that have evolved as a signal between conspecifics. The signal elicits a specific reaction, for example a stereotyped behavior (*releaser effect*) and/or a developmental process (*primer effect*), from a conspecific. Responses to pheromones are usually innate, and vary depending on the context and the receiver.

Several pheromones are not single compounds but rather a species-specific combination of molecules in a precise ratio. This combination is

the pheromone itself, although sometimes it is called a *multicomponent pheromone* or *pheromone blend*. The majority of pheromones operate by means of the conventional senses of olfaction and taste, but some pheromones (*allohormone pheromones*) may be ingested and act directly on the brain or other tissues.

Pheromones include numerous compounds or combinations of molecules, and serve a wide variety of functions. Some pheromones are specific to different life stages or castes. One key feature of pheromones is that they are “anonymous”: a given pheromone is the same in all individuals within a species of the same type (e.g., male or female) or physiological state (e.g., fertile or nonfertile), and it conveys a stereotyped message that is independent of the individual producing it. Quantities of pheromone, however, can differ between individuals or in the same individual over time.

The formal definition of a pheromone includes both evolved emission and reception of the signal for that function. Very little is actually known about the evolution of the production and reception of many pheromones. As a consequence, Wyatt (2015) proposed an operational definition of pheromone as “fully identified molecule(s), the same across a species, in all lactating mature females for example, which when synthesized elicit the same characteristic response in the conspecific receiver as the natural stimulus.”

## Pheromones as Intraspecific Semiochemicals

A semiochemical (from the Greek: *semeion*, mark or signal) is a chemical compound involved in the chemical interaction between organisms (reviewed by Wyatt 2014). In the context of semiochemicals, pheromones are molecules that have evolved as signals for communication and used *within* a species. They are emitted by an individual and received by a second individual of the same species, in which they cause a specific reaction, such as a stereotyped behavior or a developmental process.

According to Wyatt (2010), pheromones and so-called *signature mixtures* are two distinct concepts: pheromones can be defined as species-wide signals, while *signature mixtures* may be considered variable cues for identity.

*Signature mixtures* are variable chemical mixtures (subsets of the molecules in the chemical profile of an individual animal) learned by other conspecifics and used to recognize an animal as an individual (e.g., lobsters and mice) or as a member of a social group such as a family, clan, or colony (e.g., bees and badgers).

A pheromone is a molecule (or a specific combination and ratio of molecules for a *multi-component pheromone*) that will be found, for example, in all sexually mature females. Quantities of the pheromone may differ between individuals, which may be important in mate choice, but not in ways that allow a specific female to be recognized as an individual. The pheromone signal is “anonymous”; it could be any female. In contrast, if a phenomenon, such as a male distinguishing his mate from other females, relies on a learned *signature mixture*, it would be fruitless to search for a single combination of molecules eliciting individual mate recognition across the species. It is the great difference between chemical profiles of individual females which makes learning *signature mixtures* by males possible.

### Sex Pheromones

Sex pheromones are chemical compounds, or blends of compounds, emitted by an individual of one sex for the purpose of inducing sexual behaviors by members of the opposite sex; in other words, sex pheromones are pheromones that attract the opposite sex for mating (Teal 2008). Sex pheromones act as *sexual attractants* when they induce the receiving sex to move toward the releasing sex or as *copulatory stimulants*, or *aphrodisiacs*, when released or perceived in close proximity to the receiving sex to induce a receptivity or copulatory behavior (Teal 2008).

Sex pheromones are the only pheromones which are shared by all insect orders. This originates from the universal need to reproduce and the development of chemosensory organs early in the evolutionary history of Hexapoda. In both vertebrates and invertebrates olfactory signals play an important role in synchronizing breeding efforts with social and environmental circumstances. Chemical signals, therefore, support

various aspects of mate discrimination and sexual behavior (Keller et al. 2010).

Pheromones are also important for pre-mating isolation and speciation in both vertebrates and invertebrates (reviewed by Smadja and Butlin 2009). Most animal species have chemosensory barriers at some level or other. Even animals which are well known for courtship songs or visual displays may also use chemosensory cues for pre-mating isolation; for example, this is the case with grasshoppers and brightly colored cichlid fish (reviewed by Wyatt 2014). Behavioral changes are usually the initial triggers for population divergence, and altered recognition and response to chemical cues are expected to be involved in numerous behavioral changes. These can lead to behavioral isolation, reduction of attraction between members of different species, and even the prevention of courtship and copulation (Wyatt 2014).

### Aggregation and Host-Marking Pheromones

As far as cues for aggregation are concerned, chemical cues are very important for animals. In insects, many aggregation pheromones are used for mating, feeding, or oviposition, and may be explained by eavesdropping of sex pheromones intended for the opposite sex. Host-marking pheromones deposited by female insects can also be explained by individual advantage to both the marking and responding females (Wyatt 2014).

Aggregation pheromones lead to the establishment of animal groups near the pheromone source, either by attracting conspecifics from a distance or causing them to stop when they pass by (Wertheim et al. 2005). In contrast to sex-attractant pheromones (which attract only the opposite sex), aggregation pheromones can attract both sexes; in other words, aggregation pheromones are effective where either both sexes respond or the responder is the same sex as the emitter.

Tristram Wyatt (2014) noted that there are three different mechanisms underlying pheromone-mediated aggregations. First, individuals may aggregate in order to benefit from living in a group. For example, pheromone-induced winter aggregations of ladybird beetles facilitate collective success by means of amplification of

aposematic display, survival in harsh winter conditions, and increased mating. Second, aggregation pheromones may be the response of eavesdropping conspecifics. For example, males may respond to sex pheromones, which have been released by other males to attract females in order to mate with those females. By contrast, for instance, host-marking pheromones, deposited on hosts by insects parasitizing fruits or caterpillars, may cause dispersion as they deter other females from laying eggs in that host. Third, the so-called Allee effects may explain the evolution of many aggregation responses to pheromones. Basically, while the negative effects of overcrowding are obvious, the effects of being “undercrowded” (i.e., to have a population density that is too low) are less evident. For example, a lone animal may be more vulnerable to predators or unable to find a mate. Allee effects are often revealed by lower reproductive rates per individual at low numbers or densities of conspecifics.

However, the functional roles of aggregation pheromones differ widely (reviewed by Cardé 2014). For instance, in ladybird beetles, both sexes emit the pheromone, the aggregations persist for several months over winter, and mating only occurs when beetles disperse in the spring; the aggregation pheromone promotes clustering in autumn and does not induce mating. In long horned beetles, male-released pheromone induces attraction of both sexes, resulting in mating and relatively persistent aggregation. In bark beetles, the pheromone promotes mate finding and then mass attack of the host tree.

### Pheromones in Social Organization

Semiochemical signals are also important for kin recognition, mate choice, and other socio-sexual behaviors. A common feature of recognition by conspecifics is the ability to learn odor cues at a certain life stage. Social insects (e.g., ants, bees, wasps and termites) use hydrocarbon odor cues on their cuticles. Colony odors are usually the combination of secretions under genetic control and odors gained from the environment. For instance, the mixture of odors may serve to mask the underlying genetic heterogeneity of a nest of honey bees, which share a mother but have different

fathers. Similarly, social mammals use mixtures of odors that are equally complex. In both insects and mammals, the odor signatures lead to acceptance by the rest of the social group (reviewed by Wyatt 2014).

Recognition of kin or fellow group members is central to social and altruistic behavior toward kin, whether the group is an enormous colony or just a small family. However, recognition phenomena are thought to rely on learning and chemical cues predominately. The signature mixture molecules, learned by receivers as the template for recognition, can be produced by the sender itself or acquired from diet or local environment.

Pheromones are important for social insects, which live in colonies, and for social mammal species, where individuals share and defend the same territory. In some societies of social insects and mammals, cooperation includes reproductive division of labor: some individuals (helpers or workers) do not themselves reproduce but instead help to rear the offspring of other group members (their sisters or mothers). Such altruistic reproductive behavior can persist because of kin selection, which allows the helpers to gain their inclusive fitness indirectly by rearing copies of their genes in their brothers and sisters (Bourke 2011). In social insects pheromones are commonly used to signal queen status or to suppress reproduction in subordinates; however, little is known about how this works in comparable mammal societies (Wyatt 2014).

Nevertheless, even in the most cooperative societies, genetic conflicts of interests are inevitable. In particular, group members can compete over access to reproduction. In those social insect societies in which almost all individuals are potentially able to reproduce, and in the majority of mammalian societies, violent fighting determines who reproduces. In some insect societies, where considerable morphological differences between the queen and workers are apparent, pheromones produced by the dominant female settle the dispute by stopping subordinate females from reproducing. However, it appears that rather than being controlled by chemical manipulation, the queen’s pheromones act as honest signals (Wyatt 2014).

In highly social mammals such as primates, various studies (reviewed by Vaglio et al. 2016) suggest that the role of chemical communication in the regulation of socio-sexual behavior has been underestimated. For instance, chemical signals are known to advertise reproductive state, dominance rank and individual identity in prosimians (ring-tailed lemurs and sifakas) and New World monkeys (marmosets and tamarins); they also advertise sex, age, and family membership in both New World monkeys (owl monkeys) and Old World monkeys (mandrills). Additionally, odor profiles may reflect individual genotype and genetic similarity in ring-tailed lemurs and mandrills, and also mediate reproductive suppression of subordinate individuals by dominants in marmosets and mouse lemurs. However, although chemical signals play an important role in primate communication there is no robust bioassay-led evidence for the claims that pheromones exist in humans (Wyatt 2015).

### Alarm Pheromones

Several animals respond to the threat of predation by producing alarm signals that warn other individuals of the presence of danger or reduce the success of predators. These alarm signals may be visual or auditory, as well as chemical. Alarm pheromones are chemical substances, produced and released by an organism, that warn or alert another individual of the same species of impending danger. They are widespread, especially among insects and aquatic organisms (Verheggen et al. 2010).

Various studies (reviewed by Verheggen et al. 2010) address chemical identification of alarm pheromones and their impact on the behavior of nearby individuals. In order to conclude that a specific chemical compound acts as an alarm pheromone, it is generally considered necessary to demonstrate that (i) the compound is released exclusively under exposure to hazard, (ii) the signal is perceived by conspecifics, and (iii) it induces in the receiving individuals behavioral reactions similar to those induced when directly exposed to the same danger. On the other hand, adaptive responses to the reception of an alarm pheromone may be classified as evasive (i.e.,

receivers flee from the pheromone releaser) or aggressive (i.e., receivers move toward the signal and attack or harass the predator).

Alarm signals offer a great challenge to evolutionary explanations of behavior (Bradbury and Vehrencamp 2011) as animals make alarm signals to warn conspecifics of danger but they do so at risk to themselves. However, several animal species release alarm pheromones for the benefits to kin, which may be direct family members or fellow members of a social insect colony.

In social insects, alarm pheromones are the most commonly produced class of chemical signals after sex pheromones, and have evolved independently within all taxa. They are likely to have evolved as secondary or modified uses of existing compounds. Two common evolutionary routes, both linked to predation, consider alarm pheromones from either chemical compounds used in defense or those released by injury. There is also a third different route, where alarm responses have evolved from cues of injury of unrelated conspecifics or even individuals belonging to other species. These cues, which are also called “*public chemical information*” and can be found in a wide variety of aquatic species, are not considered to be evolved signals and so they are not pheromones (Wyatt 2014).

Alarm pheromones have been found in both invertebrates and vertebrates, with great diversity of alarm signaling systems occurring in presocial (aphids) and social (ants, termites and honeybees) insects; vertebrate animals; and even plants (reviewed by Verheggen et al. 2010). The chemical composition of alarm pheromones is highly variable; some of these pheromones can be composed of a single molecule and some of complicated chemical mixtures, whose activity is determined by their specific composition, the quantitative pattern of the different compounds, and the stereo-isomerism of the most abundant substances.

### Mode of Action of Pheromones

#### Evolution of Pheromones from Chemical Cues

Communicative behavior evolved from functionally different behaviors, and the evolution of

chemical cues into pheromones is no exception from this, although research has mainly focused on visual and acoustic signals (García-Roa et al. 2017). Pheromones are a very diverse group of chemical substances and the use of the olfactory system with its flexibility, using relatively non-specific receptors, makes the evolution of any chemical cue into a pheromone possible (Wyatt 2014). A chemical cue is any chemical compound that is used to the receiver's advantage, but has not evolved for this purpose, for example, how the mosquito finds its host via the detection of CO<sub>2</sub>. A pheromone however is all about communication, where the signal alters the behavior of the receiver, and this response leads to a change in the chemical signal in the originator (Wyatt 2010).

Bradbury and Vehrencamp (2011) discuss the evolution of pheromones following two main theories, sender pre-adaptation (sender precursor model), starting from chemical cues released by the sender, and receiver pre-adaptation, where compounds having other uses originally, for example, host or food odor, evolve to become a pheromone signal. An example of sender pre-adaptation would be chemical compounds leaking from a mature female attracting males for fertilization. A male with a mutation for higher sensitivity to detect these compounds will have more opportunities to mate, which leads to the evolution of increased sensitivity to the female's molecules through increased receptor density or specificity (Bradbury and Vehrencamp 2011). Here the chemical cue has become a pheromone. In an example of receiver pre-adaptation female moths utilize plant odors to localize suitable hosts for egg laying; this sensory bias is used by male moths to attract the females. Wittman (2016) also showed how female parasitic wasps (*Urolepis rufipes*) use the males' substrate-borne pheromones to assess male quality.

The evolution of pheromones plays an important role in species diversification. Recent work by García-Roa and colleagues (2017), using phylogenetic macroevolutionary modeling, gave a deeper insight into the extent and trajectory of diversification of animal communication, which so far had only been investigated for visual and acoustic cues. They found how multiple chemical

signals in lizards have diversified following different evolutionary speeds and directions, with some compounds being subjected to stabilizing selection, while others diversify following the Brownian motion modes of evolution.

### Pheromone Diversity and Specificity

Principally any chemical can be utilized as a pheromone if the compound(s) reliably convey a message against the background noise that can be detected by a receiver and is used to evoke a response (Wyatt 2014). Not surprisingly the chemical diversity of pheromones is large with a second key requirement being that the signal needs to reach the receiver, either directly by diffusion through the environment or indirectly through currents. These currents can be natural flow (of water/air) or even made by the sender organism themselves as described in crayfish. In terrestrial systems most pheromones require a level of volatility for dispersal (Wyatt 2014). There exist structure-activity/function relationships in aquatic systems with volatile distance cues, as well as slow diffusing peptide signals used in pheromone trails. Long-lasting pheromone signals such as territorial markers in mice are volatile but are stabilized in a protein matrix (mouse urinary proteins, MUPS, Hurst et al. 2017) that enables slow release rates and signal exclusivity.

Specificity of pheromones is often essential as predator and competitor "eavesdropping" on pheromones is widespread (Stowe et al. 1995) and can be achieved through a range of strategies such as producing an exclusive molecule usually through de-novo synthesis (Wyatt 2014). Producing exclusive compounds comes at a significant cost as it potentially requires specific synthetic capabilities, coordinated with receptor specificity, and may reduce flexibility and evolutionary change (Wyatt 2014). Utilizing common molecules that can be derived from food uptake or be metabolic by-products (secondary metabolites) is widespread and specificity of these is often achieved by the use of specific blends or bouquets of multiple compounds in specific ratios.

Alternatively animals use environmental timing such as moon cycles, daily rhythms

(zeitgeber) to ensure exclusivity through avoidance in space and time (reviewed by Hardege 1999) as these come with little to no costs. Mating in crustaceans for example is linked to the female molt and pheromones are chitin biosynthesis related, directly reflecting molt stages (Hardege et al. 2011). In polychaete worms environmental timing via moon phases enables a range of species sharing the same pheromone, just as elephants and butterflies share the same pheromones. Specificity is not always required though, coral spawning relies on a variety of species reacting to the same pheromones, thus creating multispecies mass spawning events that increase survival chances of offspring through overwhelming predator effects simply by the huge number of plankton resulting from these.

### Production of Pheromones

Just as diverse as pheromones are as molecules and in their evolutionary pathways, so is their production and secretion. Most animal species synthesize and secrete pheromones via specialized glands, others reuse substances taken up from the environment or even use compounds produced by bacteria for chemical communication.

Honeybees use their mandibular glands to produce diverse fatty acid-derived pheromones. Wu et al. (2017) used comparative transcriptome analysis to find out more about the biosynthetic pathway of these compounds and detected approximately 10,000 genes involved in mandibular glands with caste, queen loss, and maturity status being among factors that influence which of these will be expressed at any one time.

There is a huge diversity of these specialized glands, in ants for example there are more than 40 anatomically different exocrine glands, secreting hundreds of different molecules used for chemical communication (Morgan 2008), with sexual selection being the main driving force for their evolution. Philanthine wasps use their mandibular and postpharyngeal glands for pheromone production and storage. Looking at the morphology of male pheromone glands, Weiss et al. (2017) found a marked interspecific diversity in the type of associated secretory cells, but also in shape and size, concluding that evolution via

sexual selection led to this substantial diversity among these species.

Some moths and butterflies are examples of species that reuse molecules that they take up from the environment and either use unchanged or as a precursor during biosynthesis, emitting them via specialized organs (Wyatt 2014). An example for this are danaine butterflies, where the males use pyrrolizidine alkaloids as precursors to produce dihydropyrrolizines that act as sex pheromones in these species. The production and emission of these substances takes place in their two specialized androconial organs (Honda et al. 2016).

A well-known example of the use of compounds produced by bacteria is the aggregation pheromone of the desert locust, *Schistocerca gregaria*, guaiacol (2-methoxyphenol), causing the congregation of huge swarms. This pheromone is produced by the gut bacterium *Pantoea agglomerans* (Enterobacter) and emitted via fecal pellets (Pener and Simpson 2009 reviewed in Wyatt 2014).

Generally, the metabolic cost of pheromone production is low, compared with for example acoustic signals, where energy for muscular activity is being used. Only small quantities of the compounds are needed and the signal can be spread passively by wind or by current (Wyatt 2014). In chemical communication, the cost of signaling varies between no cost, for example by using body odor for individual recognition, and higher cost by using specifically synthesized compounds, for example the use of proteins in mouse urine (Wyatt 2014).

### Perception and Response to Pheromones/ Releaser and Primer Effects of Pheromones

Chemoreception is working in a similar way throughout the animal kingdom, where the olfactory system is usually playing the main role in the detection of pheromones. The main olfactory system (MOS) in mammals consists of the nasal cavity with the olfactory sensory neurons (OSN), while some terrestrial mammals, as well as amphibians and reptiles, also have an accessory olfactory system (AOS), the vomeronasal organ (VNO) with its own vomeronasal sensory neurons

(VSN) (Munger et al. 2009). Insects have multiple olfactory subsystems, like antennae and maxillary palps, with the olfactory sensory neurons located on sensory hairs (Hanssen and Stensmyr 2011). Structures and connections in these olfactory sensory neurons (OSNs) work in similar ways in arthropods and vertebrates.

In both cases, the odor molecules diffuse through the pores in the cuticle of arthropods' sensory hairs or the mucus protecting the olfactory tissue of vertebrates, and attach to olfactory receptor proteins (ORs). This creates a signal that moves down a single unbranched axon directly to a specific glomerulus in the brain. These glomeruli form a layer on the surface of the olfactory bulb in vertebrates or the main part of the antennal lobe in insects (Whitman and Greer 2009). Enzymes in the insect sensory lymph and the vertebrate mucus constantly break down the odor molecules. Although the structures in vertebrates and insects show a lot of similarities, this is an example of convergent evolution as there are significant developmental differences (Imai et al. 2010).

Chemosensory receptor proteins show a huge diversity with broad, but overlapping specificities (about 1000 in mice, 60 in *Drosophila*). Each OSN expresses only a single receptor type in the “one neuron – one receptor” rule (Imai et al. 2010). Richard Axel and Linda Buck received a Nobel Prize for their work on “odorant receptors and the organization of the olfactory system,” where they first describe this variety of receptors and their genes. All OSNs of the same receptor type come together in one glomerulus. A variety of odor molecules can activate olfactory receptors in different combinations, which creates a characteristic “olfactory picture” (reviewed by Wyatt 2014).

The way animals react to pheromones is innate, but there are various individual differences according to context, for example, time of day, age, sex, hormonal status, etc. The male of the moth (*Agrotis ipsilon*) for example does not react to female sex pheromones for 24 h after mating, although their antennae still detect the molecules (Anton et al. 2007). Males and females of the polychaete (*Platynereis dumerilii*) only react to

the pheromone of the opposite sex once they reach full sexual maturity (Hardege 1999).

The reaction of an animal to pheromones can be described in two ways, the immediate behavioral response (releaser effect) and the longer lasting physiological response, often mediated by hormones (primer effect), as for the first time introduced by Wilson and Bossert in 1963. Primer and releaser effect of pheromones is not mutually exclusive; some pheromones can have both effects. An example for this is how the male mice pheromone attracts females and causes aggression in rival males (releaser effect), but also accelerates puberty in young females and estrus in mature females (Novotny 2003). Villar and Grozinger (2017) hypothesize the queen social pheromone of the honeybee (*Apis mellifera*), 9-ODA (9-oxo-2-decenoic acid), evolved from a sex pheromone of its solitary ancestors. This substance has a primer effect on the physiology of the worker bees, but also attracts males during mating flights.

These few examples show the large variety of perception and response to pheromones within the animal kingdom, but at the same time highlight the similarities and convergent evolutionary pathways in this fast developing field of research.

## Applications of Pheromones

The use of pheromones to control pest species, especially insect pests, and the use of pheromones in breeding programs have been the driving forces in pheromone research from the early stages in this field in the 1960s (Howse et al. 1998). Bombykol, the first identified pheromone in the silkworm moth, *Bombyx mori* (Butenandt et al. 1959), is a good early example of the efforts to use chemicals to enable breeding of the moth to produce silk (Witzgall et al. 2010). Today the use of pheromones is an established technique for pest control combining pheromones with other techniques (trapping, deterrents, crop rotation, sterilization, pathogens, and insecticides) in what is known as integrated pest management (IPM), and they are also used to control invasive species (Wyatt 2014).

In IPM pheromones and chemical signals are employed to either monitor, to reduce the impact of, or to eradicate pest species (Howse et al. 1998). Mass trapping aims to “lure and kill” a pest, such as the removal of palm weevils in Costa Rica, where *Rhynchophorus palmarum* were caught to prevent the spread of a nematode, *Bursaphelenchus cocophilus* for which the weevils are a main vector. While mass trapping has been used successfully in many insect pests, aquatic examples are rare with only the use of migratory pheromones in sea lamprey successfully used at a large scale (reviewed by Witzgall et al. 2010 and by Wyatt 2014).

Mating disruption is a technique designed to prevent the sexual partners to locate each other by simply applying a large density of pheromone-coated pellets with slow release formulations. The many resulting odor trails have so many crossing points that the sex searching (usually males) are becoming confused and eventually stop searching (reviewed by Wyatt 2014). This technique has been applied routinely in vineyards to reduce densities of grapevine moths, and codling moths in orchards (Witzgall et al. 2010).

Push-pull approaches make use of an attractant (either sex pheromone or food signal to pull) and a deterrent (usually predator odor), often using pheromones in combination with other cues to push pests away from crops and concentrate them in areas where attractant traps are located (reviewed by Khan et al. 2012). Attraction of beneficial insects used as natural predators of pests is also achievable via pheromones (Wyatt 2014).

Farming and aquaculture benefit from pheromones through improved breeding programs, control of diseases through removal of vectors, or the development of resistant lines. Recent work includes the production of plants that produce insect pheromones such as aphid cues or moth sex pheromones, all based on the initial discovery that wild potatoes produce the aphid alarm pheromone (E)- $\beta$ -farnesene (reviewed by Wyatt 2014). A wide range of genetically modified crops and animals are expected to arise from our growing understanding of pheromone chemistry (Witzgall et al. 2010), and applications

potentially also include the use of pheromones in humans to, for example, influence mother-child interactions (Vaglio et al. 2009), develop contraception techniques, and influence human psyche (Wyatt 2014) – a field traditionally exploited by the perfume industry.

## Pheromones in a Changing World

Chemical signals are not only released into the environment where they can be impacted upon, but every step of olfactory communication, from production of signals, transfer through the environment, detection, perception, and responses upon pheromones, can potentially be interfered with (Rosenthal and Stuart-Fox 2012). Anthropogenic influences can fundamentally disrupt chemical communication systems with the terms “olfactory disruption” and “infodisruption” describing how human activity interferes with animal signaling systems. Toxic compounds including heavy metals, endocrine disruptors, plasticizers, and pesticides can reduce pheromone production either directly (signal biosynthesis) or by reducing fitness of individuals, which also affect signal reception, processing, and animals’ behavioral responses (Rosenthal and Stuart-Fox 2012).

Disturbing communication systems can have significant impacts upon ecosystem functions impacting not only on animal interactions (Boullis et al. 2016), but all aspects of animals’ utilization of chemical cues such as multi-trophic interactions, leading for example to altered insect pollinator communities. The detection of pathogens through odor profiles is also influenced by the effects of climate change such as increasing temperatures, and noxious gases. Changes to insect chemical communication systems are therefore also regarded as potentially impacting upon their use in Integrated Pest Management programs (IPM), a key practical application of chemical signals (Boullis et al. 2016).

The impacts of climate change especially the increase of atmospheric CO<sub>2</sub> are especially well documented in marine ecosystems, where a recent review by Clements and Hunt (2015) revealed that over 150 studies published between 2010 and

2015 show altered animal behavior upon changes in seawater chemistry with over half of the tested behaviors impacted negatively. In marine fish, changes of responses to olfactory signals seem to be based primarily on altered neurotransmitter function that occurs when animals compensate for the increase in seawater pCO<sub>2</sub>, while in crustaceans a decrease in seawater pH changes the chemical signals themselves (charge distribution and conformation, Roggatz et al. 2016).

To date, it is unclear whether pheromone signaling systems can adapt fast enough to rapidly increasing effects of climate change or whether pheromones possess the plasticity to negate impacts of climate change (Wyatt 2014), and at which costs adaptation may work.

## Conclusion

The use of chemical signals such as pheromones is crucial for the functionality of animal communication systems. These info-chemicals control all types of behavior and physiology in almost all organisms at all trophic levels. There is a significant diversity in the chemistry, and their physiological and biological effects and complex mechanisms of action for pheromones have evolved. Pheromones can be used to manipulate animals and ecosystem functions and services, with insect pest control and invasive species control forming a driving force in research efforts. Almost all pheromones, and with it the biological functions they control, can be affected by human activity and environmental stressors. Climate change represents a challenge for pheromone communication systems, and as such the stability of animal behavior, a key functional trait that controls species interactions.

## Philopatry

Ming Fei Li  
Department of Anthropology, University of  
Toronto, Toronto, ON, Canada

### Definition

Tendency for an animal to remain or return to their natal site or group.

### Introduction

Philopatry and dispersal are complementary behaviors and as such both will be discussed extensively. Individuals can disperse and leave their natal site or group, or they can stay. Individuals that remain and breed in their natal site or group are referred to as philopatric. This entry will explore examples of philopatry, sex-biases in dispersal, the main reasons for dispersal, and the implications of philopatry for sociality.

### Natal Philopatry

Natal philopatry refers to when an individual remains in their place of birth or returns there after being away for some period of time; the latter is also known as natal homing. The often-cited example is the sea turtle, where females travel great distances to lay their eggs at the location which they had hatched. Loggerhead sea turtles

(*Caretta caretta*) are likely relying on the Earth's geomagnetic field to navigate their way back to their natal site (Brothers and Lohmann 2015). Many migratory species also exhibit natal philopatry, such as fish and birds (Greenwood 1980; Thorrold et al. 2001). Natal homing may be favored due to familiarity with the natal environment and to maintain genetic distinctiveness from other populations or species. Philopatry can also refer to remaining in the natal social group. While some individuals disperse from their natal group around the onset of sexual maturity, others remain in the same group throughout their life (Gandon 1999; Greenwood 1980). Dispersal can be age-biased, where juveniles disperse from the group and adults are philopatric (Jack and Fedigan 2004; Pusey and Packer 1987). Dispersal can also be sex-biased, where females disperse while males remain philopatric or vice-versa (Greenwood 1980; Perrin and Mazalov 2000).

### Reasons for Dispersal

The two main reasons for dispersal are kin competition and inbreeding depression. Since offspring have a high degree of relatedness with parents and kin in their natal group, kin competition decreases inclusive fitness (Gandon 1999). Kin competition includes competition for resources (e.g., food, space) and competition for mating partners. Particularly in species with polygynous or promiscuous mating strategies, males' reproductive success is dependent on securing mating opportunities. Thus, it makes sense for adolescents who are reaching sexual maturity to leave their natal group in order to allow close kin to have more mating opportunities thereby increasing their inclusive fitness (Perrin and Mazalov 2000; Waser and Jones 1983). Due to the high degree of relatedness between an offspring and other members of the group, there is a chance for inbreeding depression if the offspring remains in the natal group (Gandon 1999; Greenwood 1980; Perrin and Mazalov 2000). Inbreeding depression is any detriment to an individual's fitness caused by genetic similarities of the parents. To avoid inbreeding

depression, one or both sexes will leave to prevent mating with close kin.

Dispersal may occur due to other factors besides kin competition and inbreeding depression. For example, infanticide is most likely to occur during male takeovers, whereby the invading male targets unrelated infants. One counterstrategy is for the mother to temporarily or permanently disperse from her group to avoid infanticidal males. In some species, such as ursine colobus monkeys (*Colobus vellerosus*), females can be facultative dispersers, which means that while males always disperse from their natal group, females can either disperse or remain philopatric. In ursine colobus, females were found to be more likely to disperse during slow male takeovers than quick male takeovers, likely due to the social instability and risk of getting caught in agonistic encounters during slow takeovers (Sicotte et al. 2017). Thus, the decision to remain philopatric can be flexible and be dependent on external factors.

It is important to add that sometimes members, usually higher-ranked individuals, will forcibly evict other members to avoid competition. Therefore, dispersal is not always peaceful or voluntary (Pusey and Packer 1987). In fact, dispersal can be extremely costly since the dispersing individual has to explore new and potentially dangerous environments. In addition, individuals attempting to join a new group are often attacked by unwelcoming resident members.

### Sex-Biases in Dispersal

Among social animals, there is usually a tendency for one sex to disperse while the other one remains in the natal group. There is a notable correlation between mating systems and sex biases in dispersal (Greenwood 1980). The majority of bird species are monogamous and have male-philopatry while the majority of mammals are polygynous or promiscuous and have female-philopatry. However, there are also cases of female-philopatry in monogamous species and male-philopatry in polygynous

and promiscuous species, therefore, it is unlikely that mating systems alone determine the sex-bias in dispersal. Other alternative explanations for the sex-bias in dispersal focus on the relative strength of resource defense and mate defense (Greenwood 1980). Strong resource defense (usually by males) will attract females, and since it is very costly for the male to abandon his monopolized physical resources, females are more likely to disperse. Strong mate defense (again usually by males) usually accompanies species where males increase their reproductive success by gaining more access to mates, therefore males will likely disperse according to the distribution of females. Sex-biases can also be influenced by the duration of male tenure (Clutton-Brock and Lukas 2012). If male tenure is shorter than the time it takes for females to reach sexual maturity, then females are likely to be philopatric because they can avoid mating with the resident breeding male who is usually their father. If male tenure is longer than the time it takes for females to reach sexual maturity, then females are more likely to disperse to avoid inbreeding depression and mate with unrelated males.

### Implications for Sociality

Which sex remains philopatric has a strong influence over the social organization of the species. Members of the philopatric sex are more likely to be cooperative with one another, form strong long-term social relationships, and maintain a stable dominance hierarchy. In cercopithecine monkeys, such as vervet monkeys (*Chlorocebus pygerythrus*), females are philopatric and remain in their natal group often from birth until death. Thus, vervet monkey groups are matrilineal and females exhibit strong social bonds. The higher-ranking females are usually older individuals who have been in the group the longest and know the most about the environment and thus represent a valuable source of ecological knowledge. In addition, female members are likely related to one another so altruistic acts such as alloparental care and group

defense against aggressive males are favored to increase inclusive fitness. In contrast, another species of primate, the chimpanzee (*Pan troglodytes*) is male-philopatric and the males, who are usually related to one another, form the core cooperative unit. Therefore, the philopatric sex generally represents the stable, long-term unit, while the sex that disperses represent the transient, short-term addition to the group.

## Conclusion

Dispersal has costs and benefits, but the benefits must outweigh the costs in order for this behavior to persist in so many animal taxa. This entry defines natal philopatry, describes reasons for dispersal, the sex-biases in dispersal, and explores how philopatry influences social relationships. It is apparent that no singular explanation has been able to explain the patterns and reasons for dispersal, so perhaps it is the interaction of multiple factors which accounts for the variability in this behavior.

Photoperiodism is the ability of plants and animals to measure and respond to duration of light and dark in a day, or length of day and night cycle in a day, season, or year, i.e., photoperiod.

## Photoperiodism in Plants

In plants, the vegetative phase switches over to reproductive phase at particular period of day length known as critical light period or critical day length (Hopkins et al. 2009; Sinha 2004; Taiz et al. 2015). The phenomenon of photoperiodism in plants was first discovered by Somewhere in 1920s (Garner and Allard 1920) while working with Biloxi variety of soybeans and ‘Maryland Mammoth’ variety of tobacco (Hopkins et al. 2009). They discovered that these plants could be made to flower only when the daily exposure to the light was reduced below a certain critical duration.

Depending upon the duration of photoperiod, the plants are classified into three categories:

1. Short-day plants (SDP)
2. Long-day plants (LDP)
3. Day-neutral plants (DNP)

**Short-Day Plants (SDP):** These plants require a relatively short daylight period (usually 8–10 h) and a continuous dark period of about 14–16 h for flowering (Hopkins et al. 2009; Sinha 2004; Taiz et al. 2015). In SDP, the dark period must be longer than a certain critical length in order to flower. If the dark period is interrupted midway by even a single flash of light, flowering is inhibited. Short-day plants even flowers when kept in continuous darkness along with sucrose. Length of day plays insignificant role in flowering. The short-day plants may thus be called long-night plants. Common examples of short-day plants are chrysanthemums, cocklebur (*Xanthium strumarium*), tobacco (mutant ‘Maryland mammoth’, *Nicotiana tabacum*), soybean (*Glycine max*), sugarcane (*Saccharum officinarum*), rice (*Oryza sativa*), etc (Hopkins et al. 2009). They normally flower in the early spring or autumn.

**Long-Day Plants (LDP):** These plants require a photoperiod of more than a critical length, which varies from 4 to over 18 h. They require either a relatively small period of darkness or no darkness at all. In fact it has an inhibitory effect on the flowering of the plants. A long-day plant can be made to flower even under short-day conditions, if a flash of light is given to the plant during long dark period. Examples of long-day plants (LDP) are barley (*Hordeum vulgare*), spinach (*Spinacia oleracea*), radish (*Raphanus sativus*), henbane (*Hyoscyamus niger*), onion (*Allium cepa*), carrot (*Daucus carota*), cabbage (*Brassica oleracea*), etc. They normally flower in late spring or early summer.

**Day-Neutral Plants (DNP):** These plants flower in all possible photoperiods ranging from few hours to 24 h of uninterrupted light exposure. Examples of such plants are bluegrass (*Poa annua*), corn (*Zea mays*), balsam (*Impatiens balsamina*), bean (*Phaseolus* sp.),

cotton (*Gossypium hirsutum*), cucumber (*Cucumis sativus*), potato (*Solanum tuberosum*), strawberry (*Fragaria chiloensis*), and tomato (*Lycopersicon esculentum*).

### Perception of Photoperiodic Stimulus and Presence of a Floral Hormone

Photoperiodic stimulus is perceived by the pigment phytochrome present in the leaves (Hopkins et al. 2009; Taiz et al. 2015). This pigment is present in plants in two interconvertible forms, red-light-absorbing form, Pr ( $P_{660}$ ), and far-red-light-absorbing form, Pfr ( $P_{730}$ ). One form of phytochrome is  $P_{730}$  nm which absorbs light at 730 nm, and other is  $P_{660}$ , which absorbs light at 660 nm. These two forms of the pigment are photochemically interconvertible (Hopkins et al. 2009; Taiz et al. 2015). When  $P_r$  form of the pigment absorbs red light (660–665 nm), it is converted into Pfr form. When  $P_{fr}$  form of the pigment absorbs far-red light (730–735 nm), it is converted into  $P_r$  form. The  $P_{fr}$  form of the pigment gradually changes into  $P_r$  form in dark.

Under long-day photoperiods, Pfr form of pigments accumulates for a longer time and stimulates flowering of long-day plants and inhibits flowering of short-day plants. Under short photoperiods,  $P_{fr}$  gradually changes into  $P_r$  and is retained for a longer time and stimulates flowering of short-day plants. It is believed that phytochrome mediates change in the pattern of metabolism of a flowering hormone called florigen in the leaves (Hopkins et al. 2009; Sinha 2004; Taiz et al. 2015). This substance is synthesized in favorable photoperiodic conditions. Florigens are then translocated through phloem to the apical and lateral bud primordia, subsequently causing initiation of floral primordia. Subsequently the vegetative bud primordia will be converted into floral buds.

### Importance of Photoperiodism in Plants

Knowledge of photoperiodism can be used in agriculture and horticulture. By controlling the photoperiod, some plants where vegetative stage

is important (e.g., many vegetables like spinach, radish, carrot, sugarcane) can be kept in vegetative phase to obtain higher yield of tubers, rhizomes, corms, bulbs, etc. or keep the plant in reproductive phase to yield more flowers and fruits during their off-season. A plant can also be made to flower throughout the year by providing favorable photoperiod, e.g., annuals.

### Photoperiodism in Animals

Animals particularly mammals cope up with seasonal fluctuations in environmental conditions such as temperature and food availability by exhibiting seasonal cycles of physiological, behavioral, and morphological changes (Anderson 2000; Dahl et al. 2000; Vasantha 2016; Walton et al. 2011). They limit the energy demanding processes and activities such as reproduction, preparation for migration, and other extensive activities and instead focus on seasonal fluctuation adaptations. Thus, for an individual to be reproductively successful and subsequent fitness, correct timing of physiology and behavior is crucial.

### Photoperiod and Reproduction

**Mammals:** Many mammals' seasonal photoperiod marks the reproduction successes (Anderson 2000; Dahl et al. 2000; Vasantha 2016; Walton et al. 2011). They detect and respond to environmental cues that indicate the arrival or departure of seasons, and accordingly it can be breeding season or non-breeding season (Anderson 2000; Dahl et al. 2000; Vasantha 2016; Walton et al. 2011). For mammals, spring is the most favorable time of the year to breed, and the length of the gestation period determines when mating occurs. Based on the photoperiodic conditions at the time of the initiation of the mating, seasonally breeding mammals are called "long-day" (i.e., with long or increasing photoperiod) or "short-day" (with short or decreasing photoperiod) breeders (Anderson 2000; Vasantha 2016).

The breeding season of short-day breeders occurs mainly when days are shorter with longer period of darkness. They undergo gestation

lengths of 5–6 months, and their offspring are usually born in spring. Examples of short-day breeders include sheep, goat, and deer. During late winter to spring, they remain in a period of reproductive quiescence because of increased photoperiod. Ewes have relatively long periods of gestation and their breeding season is in autumn and give birth to lambs in the spring season when plenty of food is available and the other environmental conditions are favorable for their growth and development (Walton et al. 2011). Goats' breeding season occurs in autumn and winter. Long-day breeders breed when the period of daylight is longer than darkness. Examples of long-day breeders are horse, rabbit, hamster, mink, etc. They have either short gestation lengths or long gestation lengths and breed in late winter or spring, with their offspring also being born mainly in spring. They remain in anestrus during the short days (Vasanth 2016; Walton et al. 2011). Rabbits are shown to improve the quantity and quality of spermatozoa present in the ejaculates when exposed to long days (16HL:8HD) in comparison with those collected in rabbits exposed to short daylight (8HL:16HD) (Mousa-Balabel and Mohamed 2011).

**Avians:** Birds are not capable of storing nutrients for raising their young as mammals and depend on specific protein-rich food resources, which are often only available during a short period. Abundant food availability triggers a positive stimulus for initiating egg-laying. Birds perceive the temporal seasonal change in day length as an environmental cue required for initiating spring migration and gonadal development before the advancement of favorable breeding seasons. In migratory songbirds, day length acts as a synchronizer, entraining endogenous circannual rhythms of gonadal maturation, molt, and nocturnal migratory activity (Dawson et al. 2001).

## Mechanism of Photoperiodic Stimulation

Most seasonal breeding mammals possess a self-sustained endogenous rhythm of seasonal reproductive activity, which is either synchronized or

entrained by photoperiod (Anderson 2000; Vasanth 2016; Walton et al. 2011). The changing photoperiod acts as a bioregulator of reproductive activity and fertility in mammals (Dahl et al. 2000; Walton et al. 2011). Light is perceived by the eyes and stimulates the photoreceptors present in the retina. Through the optic nerve, neural information is transmitted to the suprachiasmatic nucleus (a group of neurons located in the ventral side of the encephalon). This information is further transmitted to the stellate ganglion (anterior cervical ganglion) and then to the pineal gland (an endocrine gland). Pineal gland translates neural stimuli mediating photoperiod into hormonal stimuli (Walton et al. 2011). It secretes a particular "photoperiodic hormone" called melatonin (*N*-acetyl-5-methoxytryptamine) (Vasanth 2016; Walton et al. 2011).

Melatonin is secreted when the animal is in a dark environment and inhibited by daylight (Clarke et al. 2009; Vasanth 2016). High melatonin concentrations in blood transmit the information that the animal is in a dark environment to the animal's organs and tissues. The critical information is coded by the duration of nocturnal melatonin secretion, which is proportional to the length of the night and decoded by the melatonin-binding sites in the central nervous system. Thus, melatonin can either inhibit ("long-day breeders") or stimulate ("short-day breeders") reproductive activity (Vasanth 2016).

Sexual maturation and reproductive functions in seasonal breeding mammals are dependent on the activation of melatonin receptors and binding sites in the hypothalamic-pituitary-gonadal (HPG) axis. Hypothalamus secretes pulsatile gonadotropin-releasing hormone (GnRH) into the hypophyseal portal system and stimulates the release of gonadotropins (luteinizing hormone (LH), follicle-stimulating hormone (FSH)) from the anterior pituitary (Clarke et al. 2009; Walton et al. 2011). Gonadotropins help in development and maintenance of mature gonads. The seasonal change in sensitivity to estrogen is the major mechanism for shift from breeding to non-breeding. Non-breeding season is characterized by an increase in negative feedback effect of estrogen on GnRH and gonadotrophin secretion. This results in reduced frequency of GnRH

pulses, reducing the secretion of LH and FSH (gonadotrophin), thereby causing the gonadal regression (Clarke et al. 2009; Walton et al. 2011).

In long-day breeders, the inhibitory effect of the pineal gland occurs during the short days of late fall and winter. Once the season changes with increasing photoperiod into long days, the pineal gland becomes less active, and thus the secretion of melatonin is reduced considerably. The inhibitory influence on the hypothalamus is removed. As a result of which, the hypothalamic releasing factors and pituitary hormones are also secreted to initiate the reproductive process for the onset of breeding. The young ones are produced during spring and summer. In short-day breeders, shorter days with more periods of darkness initiate the reproductive activity due to increase in melatonin secretion. The increased melatonin secretion reaching the hypothalamus then stimulates the pulsatile secretion of GnRH which in turn increases production of FSH and LH secretion from the pituitary gland resulting in the onset of ovarian activity and starting of the breeding season.

### Importance of Photoperiodism in Animals

Photoperiod being a constant environmental clue is a very reliable predictor of future environmental conditions (temperature), seasonal changes in climate, and food availability (Dahl et al. 2000; Demas et al. 2009). In animals, by altering the photoperiod artificially, certain activities like migration, reproduction, and changing of coats or plumage can be induced out of season (Dahl et al. 2000). The mating season of a species can be made to occur at an unusual time by manipulating daylight. Goat and sheep mating behavior can be changed by providing long periods of light followed by short periods, while mink's reproductive process can be started when daylight is increased. It also has a huge application in poultry industry as daylight affects egg-laying, mating, and body weight of the fowl. It is a useful tool to improve the lactational performance of cows.

### Photoreceptors

Gerald H. Jacobs  
Department of Psychological and Brain Sciences,  
University of California, Santa Barbara,  
CA, USA

### Definition

Photoreceptors are structures in living organisms that respond to incident light and provide signals

that serve to initiate and maintain behaviors as varied as vision, phototropisms, phototaxes, and photoperiodicities.

## Introduction

Life initially evolved by utilizing the energy inherent in light. That same energy now provides the driving force for complex biological processes as diverse as plant photosynthesis, the timing of mating seasons in animals, and the reading of this text. Each of these processes starts with a translation of light to the activation of biological signals. The structures that accomplish that task are the photoreceptors. The focus here is on visual photoreceptors, specifically, on how they evolved and the functions they have come to support.

## Evolution of Photoreceptors

Photosynthetic cyanobacteria utilize organelles (chloroplasts) to convert the energy inherent in sunlight. Having first appeared some 2.7 billion years ago, cyanobacteria are believed to be the earliest organisms to exploit light (Schwab 2012). The capture of light by animal photoreceptors is accomplished through the activation of photopigments, the light-sensitive molecules contained in photoreceptors. Animal photopigments are composed of two conjoined components: a protein, opsin, and a chromophore that, in higher animals, is an aldehyde derivative of the vitamin A obtained from diet. Opsins have a long history, having first appeared around 700 million years ago (Mya) during the very early evolution of animals (Lamb 2013).

Absorption of light energy produces a change in state of the photopigment molecule that leads to the production of a signal used to trigger cellular changes. The signal generated by the activation of an individual photopigment molecule is miniscule. Consequently, concentrating photopigment into package-like structures allows these small signals to be summed together, and this thus serves as a fundamental step toward the goal of increasing the sensitivity of an organism to light.

One such example is the eyespot, an organelle composed of numerous photoreceptive molecules that are densely embedded in supporting structures (Fig. 1a). When activated by light, eyespots can provide a direct drive to a locomotor apparatus – for example, a flagellum of the sort found in some single-cell organisms – so allowing an animal to respond to the presence of light by movements that are either directed toward or away from a light source (positive and negative phototaxis). From similar beginnings complex eyes evolved. Over time, a considerable range of structural and functional adaptations emerged in eyes that served (1) to facilitate increases in sensitivity to light, (2) to provide the ability to detect the direction of a light source, and (3) to yield the means to both analyze and signal subtle changes in the spatial, temporal, and wavelength patterns of light present in the visual environment (Nilsson 2013; Cronin et al. 2014).

The transition from eyespot-like arrangements to complex eyes followed two general pathways (Fig. 1b). In one (top, Fig. 1b), the photosensitive surface cells invaginated to form a cuplike structure that was eventually capped with a small aperture to let in outside light. Subsequent additions to this design included optical elements in the light path to support image formation across the photoreceptive surface and musculature to allow eye positioning and mobility. Camera-type eyes of this sort are predominant in present-day vertebrates. In the other design, the photosensitive sheet was bulged outward to form a convex surface (Fig. 1b, bottom). Addition of accessory optical elements and replication of individual units (ommatidia – “little eyes”), often many times over, led to a variety of different compound eyes. Compound eyes are found in most present-day invertebrates. A detailed discussion of eye formation has been provided by Land and Nilsson (2002).

Contemporary animal eyes come in a bewildering variety of structural configurations, but the photoreceptors they contain appear to have evolved according to two general plans. Visual photoreceptors require considerable amounts of membrane surface to accommodate both the photopigment and the accessory molecules

**Photoreceptors, Fig. 1** Photoreceptors. (a) In some simple organisms, such as the planarian whose outline is sketched here, photoreception is accomplished by the absorption of light by photopigment concentrated in the eyespot; (b) scheme suggested by Land and Nilsson (2002) to illustrate how a sheet of photoreceptors (center) is either invaginated (top) or evaginated (bottom) to form more complex eyes. The lines represent incoming light rays and show how the two designs can be exploited to provide

organisms information about the direction of light sources; (c) schematic drawings of vertebrate rods and cones. Photopigment is densely packed in the discs of the outer segment; (d) picture of a section taken from the monkey retina showing rods (R) and cones (C). The photoreceptors have been labeled such that the outer segments of the cones appear green while those of the rods are red. The orientation of this section is the same as that of the sketch above. Micrograph courtesy of Gabriel Luna

required to transduce signals from the activated photopigment. In one scheme, those membranes were derived from a modified cilium; hence, these are called ciliary photoreceptors. In the other, the required tissue was formed from evaginations of the plasma membrane to form minute projections, microvilli, which are grouped

together in structures called rhabdomeres; photoreceptors of this design are thus called rhabdomeric. Photopigments in the photoreceptors from these two classes generally employ opsins that are products of genes derived from two separate gene families (respectively, **c** and **r** opsins) along with distinctive transduction

machinery. Although there are notable exceptions, ciliary photoreceptors predominate in vertebrates, while invertebrate eyes most frequently contain rhabdomeric photoreceptors. How this division occurred and the functional advantages ascribed to each of the two designs are matters of active debate and discussion (Cronin and Porter 2014; Fain et al. 2010). The remainder of this discussion concentrates on the ciliary photoreceptors of vertebrates, the familiar rods and cones.

## Rods and Cones

1. *Evolution.* The earliest vertebrates and their chordate forebears featured both rhabdomeric and ciliary eyes (Morshedien and Fain 2017). The former eventually faded from the vertebrate line, and by the time jawless and jawed vertebrates diverged (~420 Mya), ciliary eyes were in full ascendance. At the same time, however, rhabdomeric photoreceptors have been retained in vertebrate nervous systems to support some specialized functions. For example, rhabdomeric photoreceptors are found in a small population of retinal ganglion cells in contemporary vertebrates. These cells possess intrinsic light sensitivity and provide signals that are used to drive photic rhythms and control pupillary constriction.

The genes that specify rod and cone photopigment opsins have been intensively studied over the past two decades. The results from that effort suggest that cone photoreceptors appeared at a point in vertebrate evolution prior to the emergence of rods. By one such estimate, rods were added to the retinal complement of photoreceptors by around 400 Mya (Lamb 2016). Although there are the notable exceptions of some vertebrates whose retinas contain exclusively cones or rods, most contemporary vertebrate retinas contain a variable mixture of the two types.

2. *Functional differences.* Nearly 150 years ago, the anatomist Max Schultze discovered that vertebrate retinas contained two structurally distinct types of photoreceptors, rods and cones (Fig. 1c, d). Based on the relative

prevalence of rods and cones in the retinas of different species, these two appeared to be linked to different sets of visual capacities with rods underlying vision in low light-level conditions, while cones supported those aspects of seeing associated with vision under daylight conditions. These functional assignments formed what became known as the duplicity theory of vision.

Over the years, numerous psychophysical studies have documented the ways in which rod- and cone-based vision differs (Lamb 2016). Some of the most prominent differences are: (1) rods support vision under low light-level conditions, whereas cones underlie vision under daylight conditions and, importantly for contemporary humans, in almost all artificially illuminated environments; (2) rod vision operates over a restricted range of intensities while that of cone vision is extremely large; (3) rod vision adapts very slowly to shifts in abrupt changes in light levels, while cone vision adapts rapidly; (4) rod vision supports low spatial and temporal acuity, while cone vision is superior in both domains; (5) color vision is characteristic of cone-based vision only. These differences between rod- and cone-based vision hold true across most vertebrate species.

Signals derived from rod and cone activation are processed through the neural networks of the visual system. Consequently, functional differences between rod and cone vision may arise directly from differences in rod and cone physiology, from differences in the processing of rod and cone signals in the visual system, or from some combination of these two. Recent technical advances have made it possible to better understand how these differences arise.

The basis for the differences in rod- and cone-based vision can be illustrated with a few examples. For instance, direct photoreceptor recordings reveal that rods respond more slowly to the onset and offset of light stimulation than do cones, so some of the difference in temporal resolution of rod and cone vision directly reflect differences in receptor physiology. Similarly, rods cease to respond

(they “saturate”) at rather modest intensities of light, and above those light levels all vision is based on cone signals alone. On the other side of the coin, direct recordings also show that rods have inherently lower electrical noise levels than cones, so they can more reliably signal the presence of very dim lights. The organization of visual systems also impacts differences in rod- and cone-based vision. In vertebrate eyes an image of the visual world is projected across the surface of the retina. Consequently, any differences in rod and cone representations across the retinal extent mean that the relative prominence of rod- and cone-initiated signals will also vary. In the human retina, for example, the image from the point of fixation is projected onto a small central region of the retina, the fovea. At that location there is a dense concentration of cones, but no rods, and thus foveal vision automatically depends on cones not rods. At retinal regions progressively distant from the fovea, rods increase in density and cones decrease and thus objects projected away from the point of fixation can influence rod and cone vision to varying degrees.

3. *Species variations.* Although mixed rod and cone retinas are characteristic of almost all vertebrates, there are striking differences in their relative representations, the organization of their visual systems, and their functional contributions to vision. Across all vertebrates, the greater representation of one or the other type of photoreceptor, the more an animal’s vision is apt to be characterized by the different properties listed above. To take a single mammalian example, the retinas of domestic cats are heavily rod dominated, while those of squirrels have relatively many more cones. In accord with that distinction, plus numerous other features of their eyes and visual systems, cats have superb visual sensitivity under very dim illumination, photic environments in which squirrels are effectively blind.

One of the most investigated cases of the behavioral consequences of photoreceptor

variations is color vision. In vertebrates, color vision is based on cone signals, but its presence requires populations of cones containing different types of photopigment. Two types of photopigment are the minimum, but different vertebrates may possess three or four or in some cases perhaps even more. The acuteness and nature of the derived color vision depends complexly on the number of different types of cone pigments, the relative representation of cones in the retina, as well as other organizational features of the visual system (Jacobs 2018). Such variations can even occur between members of the same species. Variations in human color vision provide a good example of this. Most humans have three types of cone photopigment and enjoy keen color vision, but ~2% of all males have defective photopigment genes that reduce their complement to only two types of cone pigments. Such individuals have correspondingly much more restricted color vision.

### Definition

Phylogeny is the history of evolution of a species or group with respect to its descent and relatedness with other species or groups.

## Introduction

Around 4.5 billion years ago, Earth was formed, but life emerged around a billion years ago (Dodd et al. 2017). Three major phases of evolution have been witnessed since then:

- a) The surfacing of prokaryotic organisms
- b) Followed by the emergence of single-celled eukaryotic organisms
- c) Finally, the evolution of multicellular organisms which occurred in the Precambrian period (Knoll 2003, 2015)

Henceforth, evolution can be understood as an organism's adaptive mechanism in response to the environmental conditions in due time. Evolution broadly can be categorized into three subtypes: (a) chemical evolution which denotes the formation of organic molecules in the period between the formation of earth and the emergence of the first life, (b) molecular evolution which signifies the changes that have brought about the appearance of the unicellular and multicellular organisms on Earth, and (c) Darwinian evolution which focuses on the events of speciation.

## What Is Phylogeny?

After the work of Linnaeus and others in the eighteenth century, the modern hierarchical system of classification came into existence, and the taxonomy stabilized. After Darwin's work and evolution being accepted as the critical factor behind the diversity and variation of life, phylogenies came into existence (Nixon 2001). Phylogeny can be defined as a blueprint of a historical evolutionary relationship amidst species and their higher-level taxa. The proof of this relationship is, in most cases, incomplete because a high number of the species that have ever lived on Earth are extinct, and a minimal number of them have been preserved in the form of fossil records (NAS 1999). This is why most phylogenies have been derived by using indirect evidence and are hypotheses.

However, the present life has descended from earlier ancestors is universally accepted.

## Evidence for Different Phylogenies

For the postulation of phylogenies, most applicable evidence from the varied fields of molecular genetics, paleontology, comparative embryology, and comparative anatomy are employed. Apart from these, the geographical distribution of flora and fauna along with the fossil records also prove handy in terms of pieces of evidence of phylogenies (NAS 1999; Biology Online 2020). Biochemical evidence has also played a significant role in contributing data to phylogenies. Mitochondrial DNA was found to be more prone to a mutation than the nuclear DNA, which became a valuable tool to ascertain the relationships among the groups that have diverged recently.

## Connection with Taxonomy

Before 1859, the taxonomy had no theoretical basis, and the organisms were classified on the basis of their apparent similarity. However, after the publication of Darwin's book (*On the Origin of Species by Means of Natural Selection*), evolutionary descent and relationship got acceptance for taxonomy (McNulty 2016).

## Phylogenetic Trees

This evolutionary relationship is depicted in the form of a tree diagram or a phylogenetic tree. Earlier, the phylogenetic trees formed were non-reproducible. Furthermore, these trees were constructed by indirect methods, and classification and phylogenetics were difficult to correlate through them. However, modern-day phylogenetics is different and utilizes a cladistic approach wherein molecular and morphological data is used for tree construction. There is a marked difference between cladistics and phylogenetics. Cladistics alludes only to the methods such as maximum likelihood and parsimony, which define the branching patterns; however, phylogenetics

**Phylogeny, Fig. 1** Features of the phylogenetic tree (Adapted from Sarma et al. 2019)

decodes these trees while keeping the historical patterns in mind (Nixon 2001). The essential features of the phylogenetic tree are mentioned in Fig. 1.

A speculatively rooted tree formed by using the rRNA genes, covering the three life domains viz., bacteria, archaea, and eukaryota, is depicted in Fig. 2. In this figure, the black branch connects the universal common ancestor to all the three life forms.

Another example of the phylogenetic tree, for the bacteria, is shown in Fig. 3.

## Applications of Phylogeny

Phylogenetics has its applications in a variety of fields. For instance, in the field of medical science, phylogenies can play a vital role in predicting the source and transmission of infectious diseases like dengue, influenza, and AIDS. An exciting development in phylogenetics is the application of phylogenies to various modern problems. Phylogenies that owe their development from molecular genetics have a huge role to play in the areas of hybridization and inbreeding across species, evolutionary effectiveness of endangered species, and percentage in captive breeding programs (Gittleman 2020).

## Conclusion

Phylogeny focuses on the evolutionary relatedness among the various organisms present on the earth. Although, due to the scarcity of the fossil records, it is difficult to predict the features of the extinct organisms, yet other branches like molecular

**Phylogeny, Fig. 2** Phylogenetic tree of bacteria, archaea, and eukaryota

**Phylogeny, Fig. 3** Phylogenetic tree of bacteria (Adapted from Sarma et al. 2019)

genetics are contributing toward a better understanding of the evolutionary relationship among organisms. The development of this field is increasingly important because of its applications in the field of medical science and conservation biology.

## Definition

A phylum is a scientific term grouping together related organisms on the basis of their fundamental characteristics.

## Introduction

The term phylum was coined by Ernst Haeckel (1866) and is derived from the Greek word “*phylon*,” associated with *phyle* (tribe). A phylum can be defined either by a group of organisms with a certain degree of morphological or developmental similarity or as a group of organisms with an evolutionary relationship. In classification for taxonomic rank, “Phylum” is placed below “Kingdom” and above “Class” (Fig. 1). In botany, the word division has been used instead of phylum, even though the International Code of Nomenclature for algae, fungi, and plants follows the terms as equivalent (Valentine 2004; McNeill et al. 2012a, b). On the basis of definitions, the animal kingdom, plant

**Phylum, Fig. 1** Major taxonomic ranks of biological classification

kingdom, and fungi include 32, 14, and 8 phyla, respectively.

In plant taxonomy, August W. Eichler (1883) classified plants into five groups, known as divisions, for plants, algae, fungi, angiosperms, and gymnosperms. The zoological phyla were classified to six Linnaean classes and the four Georges Cuvier embranchements. It has been estimated that, in 40 phyla, the kingdom Animalia has approximately 1,659,420 species described, which include 133,692 fossil species, and the phylum Arthropoda has the highest number of species (1,302,809 species). Mollusca (the second-largest phylum) contains 118,061 species, with more diverse species than the invertebrate phyla Platyhelminthes, Nematoda, Echinodermata, Annelida, Cnidaria, Bryozoa, and Porifera. The vertebrates (Vertebrata) lie in the subphylum Craniata of the phylum Chordata, with 85,432 species including fossil species (19,974 species), fishes (35,644 species), amphibians (7,171 species), reptiles (15,507 species), birds (11,087 species), and mammals (16,014 species).

A phylum has been also considered as a group of species that contain a similar organization of body plan (Adoutte et al. 1999). Nevertheless, in the surviving fauna, “phyla” give the impression of being the largest grouping of taxa that can readily be believed to be more firmly identified with one another than with some other group. Phyla are typically agreeable and cognizant groupings.

Morphologically, groups of taxa indicate clear affinities to one or other significant phyla. Some groups, such as onychophorans, tardigrades, acanthocephalans, pogonophorans, or echiurans, present an issue for the phylum concept (Budd 1998) and are sometimes alluded to as arthropods, rotifers, or annelids. Phyla show a developmental starting point by their characters and body design in expanded terms and are grouped in a specific order (Valentine and Hamilton 1997; Budd 1996, 1998). There is subsequently an intelligent decoupling between the body plan that the surviving individuals of a phylum share in their phylogenetic affinities to one another, notwithstanding when they are firmly connected with one another in the surviving fauna.

From past events, a clade is the appearance of a group with a specific body plan derived from that in the main branch. The individuals from a sister-

group genealogy of various clades probably were fundamentally the same as one another (Erwin 1993). The differences between that group of organisms most closely related to a particular extant phylum, and the members of that phylum itself, have been formalized into the stem-group and crown-group concepts (Jefferies 1979), which allows a more precise definition to be given to the term “body plan.” A body plan (Valentine and Hamilton 1997) is an attainment of the characteristic developmental programme or morphology or set of features plesiomorphically shared by extant taxa in a monophyletic clade. Body plan conforms precisely to the common sense view as being shared by living groups of animals and does not require any subjective assessment of the “importance” of various body features (Hawkins et al. 1997). This subjectivity has in the past led to such elasticity in the concept that it has become virtually devoid of meaning. Thus, restriction of the body plan to extant taxa enables the concept to be used practically without the problems caused by basal members of the stem groups, which may differ little from members of closely related stem groups. Apart from the origin of the entire clade, the only other objective point that can be seen in a clade is the origin of the crown group. Thus, in the view adopted here, the body plan of the extant members of a phylum can be traced back only to the origin of the crown group. The most basal members of the stem group are virtually identical to basal members of the stem group of the closest living phylum, and as such cannot be said to possess a distinctive “body plan” of one or the other of two phyla (Abele et al. 1989; Arthur 2000).

According to Runnegar (1996), the principal point of this immediate distinction is that divergence of a clade could not be the appearance of a body plan with time. This point creates conceptual difficulties to cope with the origin of phyla, the outcome being consistent over estimation of the time of their origin (Berg 2007). Under stress conditions, stems of phylum groups lead to chief reorganization of the body (Budd 1996, 1997, 1998, 1999; Mooi et al. 1994). Obliviousness of this plausibility leads, in extremis, to the inquisitive view that amid differences, phylum level seems first, trailed by class level, lower arranged level, etc. (Willis 1940; Gellon

and McGinnis 1998; Budd 1999). Stress on the stem group of a phylum is critical because it is a transformative space within which real redesigns of the body can occur, as, for example, in the arthropods (Budd 1996, 1997, 1998, 1999) and echinoderms (Mooi et al. 1994).

There are no specific motivations to believe that the real contrasts in association or advancement happen right off the bat in a clade's history, and in reality, given the level of pre-adaptation most likely required to prepare a clade, a later appearance may be more typical (Erwin 1993). As an individual from stem bunches unavoidably take after one surviving phylum more intensively than another (or perhaps one gathering of phyla more than another), and that sensibly, no fossil life form falls into a surviving phylum. It must be attributed to a stem gathering to a phylum. The presence of creatures resembling individuals from surviving phyla in the Cambrian is not really astonishing.

Notwithstanding, from the foregoing it can quickly be seen that this insignificant acknowledgment is not sufficient to set up the source of the surviving body plan, regardless of whether the creature being referred to appears similar to the surviving structures. Normally, it is the ownership of a solitary character, for example, calcium carbonate (stereostructure) in echinoderms, or division in arthropods, that permits this task (Budd and Jensen 2000). To begin with, it makes the supposition that one character can in truth stand as intermediary for the whole mind-boggling number of characters present in the surviving body plan. This idea may be valid if body designs were certain permanent edifices, so internally obligated that they could not have been procured piecemeal. Yet this supposition does not appear to be correct, and is weakest on the grounds that the fossil record can be utilized to show how this collaboration occurred (Budd 1998).

Further, by demanding a specific character, perceiving stem bunch individuals that presently cannot seem to show it might be neglected. For instance, if the stereostructure was gained inside the echinoderm stem gathering, at that point coherently there must exist a stem mass individual that does not have it: such are subsequently not

likely to be viewed as echinoderms of any kind (David and Mooi 1998). In reality, these sorts of taxa (for example, the stem-assembled arthropods *Opabinia* and *Anomalocaris*) have regularly been allocated to their very own "phylum," in light of the fact that, for this situation, they do not have the assumed key diagnostic characters of the arthropods, for example, the sclerotized exoskeleton. Third, this view neglects to perceive that characters may in actuality have had a more extensive distribution than they do today, and in this way may have been acquired in the stem gatherings of some combination of phyla at any rate, only to be lost in one of them. This probability underlies the "calcichordate" debate, with the hypothesis asserting essentially that the calcite skeleton in echinoderms had a more extensive distribution previously and was in certainty present in the stem heredity to the chordates (Gee and Janvier 1996). In the event that this is not acknowledged, creatures that have a place where it counts in phylogeny will be wrongly allocated to a surviving phylum. The presence of stem bunches, a particularly paleontological idea, implies that the neontological wording of "phyla," particularly when taken to be synonymous with "body plan," should only be connected to the fossil record (Israelsson 1999). Acknowledgment of the significance of stem bunches is accordingly basic, freely alluding to taxa as "arthropods," "annelids," or "priapulids," and ascribing taxa to these elements on deficient grounds can obscure as much as clarify developmental connections and the example of "body plan" rise.

Observation of crown-amass instead of stem-assemble affinities of a species might be troublesome, as it depends on observation of such as one synapomorphy imparted to an individual from a surviving subgathering of the phylum to which we are referring (Zhang 2013). As it were, the taxon being referred to must appear to lie either in a surviving subgathering of a phylum or in the stem gathering of such a gathering. Normally, this possibility frequently depends on a satisfactory comprehension of crown aggregate phylogeny, and particularly on establishing understanding that is occasionally alluded to in discussing body plan development. Equipped

with this understanding, it is conceivable to reexamine the fossil record of key taxa with a view to recognizing clade and crown amass starting points. In the accompanying exchange, we are not planning to display a picture of Cambrian systematics. Or, perhaps, we wish to point to its dubious points, and to take note of how preservationist a perusing of the fossil record is allowed by this vulnerability.

## Evolutionary Role of the Phylum

Evolutionary observation of gene expression can be an approach known as phylostratigraphy (Domazet-Lošo et al. 2007). The EvoDevo method is applicable for observation of developmental gene expression, but it lacks an explicit phylogenetic approach (Hejnal and Dunn 2016). Observations of evolution of development and gene expression must be studied with the same phylogenetic comparative tools used to study other traits and also reveal biological confirmation for phyla (Dunn et al. 2013; Hejnal and Dunn 2016).

According to Levin (1992), there is no clue for specific differences in the origin of phyla. Gene expression in the mid-phase of development is little conserved at evolutionary scales. Only very closely and very distinctly related animal species have been correlated: the main understanding of these changes took place by extension of species sampling to access a higher resolution of which gene expression change might occur in which branch (Fitch and Sudhaus 2002).

## Conclusion

The phylum has a key role in animal evolution and development. At the expense of all ranks, including phyla, organizational tools succeed by the support of many phylogenies, as organizational tools explaining diversity and testing biological hypotheses against the whole tree of life. Considering current animal diversity with phyla, it is difficult to explain a phylum without any evidence, to trace an evolution with the help of phylogenetic approaches. Description and resolution

of any changes that take place in the phylogeny and tree-of-life branches can be useful.

## Pigeon (*Columbidae*)

Wendy A. Williams

Department of Psychology, Central Washington University, Ellensburg, WA, USA

### Synonyms

*Columba livia*; Feral pigeon; Rock dove

### Overview

The pigeon is a member of the order Columbidae, which includes both pigeons and doves. The most common member of the order is known as the common pigeon, rock dove, or feral pigeon (*Columba livia*). It is a small- to medium-sized bird with a stocky body, small head, short beak, and short legs. They have excellent color vision, hearing, and olfactory perception. They are strong capable fliers with the ability to return home from long distances. They are monogamous breeders with pair bonds that can last from year-to-year. Within the order, there are 42 genera with 308 wild species. In addition, there are over 700 different breeds of domestic pigeons

including fancy and racing pigeons. Pigeon racing is popular sport worldwide with racing groups on six continents, excluding Antarctica. Pigeons are popular subject in both field research and laboratory investigations of behavior.

### Natural History

#### Breeds, Morphology, and Lifespan

Modern breeds of wild pigeons are divided into four subgroups: (a) typical pigeons found throughout the entire range; (b) fruit pigeons found in Africo-tropical and oriental (sic) regions; (c) large, crowned pigeons from New Guinea; and (d) tooth-billed pigeons of Samoa. Common pigeons are typically medium-sized, stocky birds with short legs, a short neck, a small head, and a straight, thin, black bill with a fleshy cere at the base of the beak. Their wings are broad; tails are wide and rounded. They are variable in color ranging from white to bluish grey to brown. Some can have iridescent patches on the head and the throat; others have dark spots or bands on their wings. The fruit-eating pigeons of the Old World can have very colorful plumage that can include blues, greens, and yellows (Lack 2003) (Fig. 1).

Depending on the species, pigeons (and doves) vary greatly in length from about 15 cm to 75 cm in length and can weigh from 30 to over 2000 g. The smallest, the plain-breasted ground dove (*Columbina passerina*), averages about 35 g; the largest, the Victoria crowned pigeon (*Goura victoria*), weighs between 2000 and 2500 g. The common rock pigeon weighs in at about 350 g. Wild rock pigeons live about 6 years. However, in captivity, rock pigeons can live an average of 15 years and to as long as 35 years (Fig. 2).

#### Distribution and Habitat

As an order, pigeons are likely the most common birds in the world. Wild pigeons are native to Europe, North Africa, and southwestern Asia, but feral pigeons are found on all continents except Antarctica (Fig. 3).

Pigeons do not occur in the driest areas of the world including Antarctica, the Sahara desert, and

the highest arctic latitudes. They inhabit nearly all habitat regions, including temperate, tropical, and terrestrial environs. They can be found in a variety of terrestrial biomes including deserts, grasslands and savannas, forests, rainforests, scrub forests and mountains, coastal regions, and wetlands.

But they occur most often in areas inhabited by humans, such as suburban and urban areas, either naturally or through human introduction. Wild rock pigeons prefer rocky coastal cliffs or open vegetation; feral birds will roost on buildings with ledges that substitute for cliffs (Lack 2003; Wells and Wells 2001).

### Evolution and Taxonomy

Pigeons are not well represented in the fossil record prior to the Miocene. Fossils of *Columba omnisanctorum* from Gargano Peninsula in Italy are dated to the Miocene (Olson 1985, cited in Pereira et al. 2007). However, more recent DNA sequencing places the origin of columbids over 42 million years ago in the Cretaceous period before subsequent mass extinctions (Pereira et al. 2007). The relationship across modern pigeons and doves and between other families such as the *Pteroclididae* (sand grouses), *Zenaidini* (quail doves), and the extinct *Raphidae* (e.g., the dodo and the Rodrigues solitaire) remains unresolved and tentative due to inconsistencies in DNA sequencing (Pereira et al. 2007) (Fig. 4).

### History of Domestication

Pigeons were one of the first domesticated species of birds. Archeological records document the venerated position of pigeons and doves as far back as 5000 BCE. Ancient Egyptians raised pigeons for ceremonial purposes and for food at least 4000 years ago. Mesopotamian kings gave homing pigeons to their royal couriers to be released in the event that the messenger was attacked to ensure the message would be resent. Kakish (2012) reviewed Iron Age evidence of ancient dovecotes throughout the Middle East, including Jordan, Iraq, Palestine, and Petra (see Fig. 5).

Minimal domestication of pigeons was well established in early Greek and Roman societies to be used for food, and they were used as religious symbols (see Figs. 6 and 7). Their homing

(Diagram of world-wide range of pigeons by Phoenix\_B\_1of 3, CC0)

abilities soon made them valuable bearers of messages. They were even used to send notifications of the names of Olympic victors.

The use of pigeons as offerings is also mentioned in the Old Testament of the Bible. For example, from Genesis 15:

(9) So the Lord said to [Abram], “Bring Me a three-year-old heifer, a three-year-old female goat, a three-year-old ram, a turtledove, and **a young pigeon.**”  
(10) Then he brought all these to Him and cut them in two, down the middle, and placed each piece opposite the other; **but he did not cut the birds in two.**

### Pigeons in Wartime

In more recent history, pigeons continued to be used to relay messages. During the Siege of Paris (1870–1871), carrier pigeons were used to convey important military successes. Taken out of Paris by balloon, the birds were released once safe passage over Prussian lines was achieved. The birds would return home to the Ministry of War, announcing the troops’ successful arrival to the battlefields. Birds were also used to convey official military dispatches back to Paris. See Fig. 8.

Well into the twentieth century, homing pigeons served both the American and British military forces by carrying important messages, maps, and even cameras across enemy lines during WWI and WWII. Pigeons carried messages on D-Day, June 6, 1944, because the allied troops operated under radio silence. Of the 52 animals that received the PDSA Dickin Medal of Honor in the UK for animal valor in WWII, 32 of them were given to pigeons.

### Pigeons in the Modern World

***Birds in the City.*** Pigeons have a penchant for urban environments. In relatively recent history, cities have commonly attempted to control feral pigeon populations through the process of selective removal of individual birds or through community pigeon shoots. Unfortunately, the consequence of culling flocks is typically the rapid replacement by birds from other areas as long as there are resources to support them (Sol and Senar 1995). Yet, the popularity of pigeon shoots remained popular through the late twentieth century.

Johnston and Janiga (1995) state that one major limiting factor of a city's pigeon colony size is food availability. Food shortages in the city of Perm, Russia, resulted in extreme population declines in two colonies over a 3-year period. According to Angal't (1989, cited in Johnston and Janiga 1995), not only did the two observed populations drop from 161 and 182 birds to 35 and 30 birds, respectively; moreover, the

**Pigeon (*Columbidae*), Fig. 7** Fifth century BCE Cyprian statue of Aphrodite holding a dove. (Fifth century BCE Cyprian statue of Aphrodite holding a dove is in the Public domain (by anonymous); statue found in the Neues Museum, Berlin)

large colonies devolved into multiple small groups of only 5 or 6 pairs of birds. Johnston and Janiga suggest that presence of solitary nesting pairs may reflect poor food resources rather than an anti-colony bias.

In Basel, Switzerland, nine lofts for wild pigeons were constructed between 1988 and 1990 to evaluate and manage the size and health of urban, feral pigeon populations by managing base food supplies. An educational campaign was launched to reduce or eliminate pigeon feeding by residents. Over a 4-year period, Haag-Wackernagel (1993) reported a 50% reduction in the 9 lofts through a combination of feeding management and the removal of 1200 eggs per year, with a corresponding reduction in the Basel pigeon population to 10,000. His data confirm that food resources can be a limiting factor for pigeon populations and an effective intervention tool for cities.

**Pigeon Racing.** The natural ability for pigeons to find their way home over hundreds of miles has interested modern scientists and modern pigeon racing enthusiasts alike. Pigeon racing has

**Pigeon (*Columbidae*), Fig. 8** Pigeon post medal for French military air communications. Bronze medallion, d. = 63 mm. become a popular sport across the globe. The American Pigeon Racing Union hosts over 700 affiliated clubs and nearly 150 affiliated breeders in the USA. Racing pigeons will typically fly between 75 and 500 miles but race longer than 1000 miles in a single race (Walcott 1996). Modern racing methods include GPS tracking and electronic monitoring of arrival times.

## Natural Behavior of Pigeons in the Wild

**Courtship and Reproductive Behavior.** Pigeons are generally monogamous birds (Wells and Wells 2001) that form long-lasting pair bonds until one of the pair dies or disappears. They will form new bonds after losing a mate but only slowly. During courtship, several males may solicit an unattached female until she selects a mate. Typical courtship behavior tends to be stereotypic; the male will spread and drag or raise his tail feathers, inflate his neck, and engage in polysyllabic cooing. Males are sensitive to the responses of their mates, and courtship rituals will be persistent as long as the female shows some interest. Bonded pairs may also engage in food sharing.

Nesting is a collaborative process. The unlined nests consists of a loose bundle of twigs, roots, and other materials and are typically placed under an overhang on a relatively flat surface like a building ledge or cave floor. Nest building takes several days, and nests are defended by both partners. Both sexes cooperate to raise the young. Clutches usually consist of two, white eggs; incubation is between 11–30 days depending on the species. Altricial young are fed crop milk – a fluid of sloughed epithelial cells from the parents' crop that is high in fat and protein. The young are cared for continuously until about 25–32 days in the summer or upward of 45 days in winter.

**Social Behavior.** Pigeons can breed year round. Some species are colonial nesters while others are solitary (Wells and Wells 2001). They show no obligatory sign of needing to breed in colonies, and yet, many do when it is advantageous to do so. According to Johnston and Janiga (1995), after the mated pair, the colony is the most social unit. Colony nesting can confer advantages

such as group foraging and communal defense against predators. Neighboring colonies may be characterized by inter-colony exchange of individuals as a result of male-to-male cross-colony interactions, cross-colony courtships, and among females that lack a pair bond.

Johnston and Janiga (1995) state that perhaps the one major limiting factor of a colony's size is food availability. Forage shortages in the city of Perm resulted in extreme population declines in two colonies over a 3-year period. According to Angal't (1989, cited in Johnston and Janiga 1995), not only did the populations drop for 161 and 182 birds to 35 and 30 birds, respectively; moreover, these previously large colonies devolved into multiple small groups of only 5 or 6 pairs of birds.

**Feeding and Foraging.** Worldwide, most pigeons forage on the ground, eating mostly seeds; some eat fruit and will forage in trees and bushes. Few pigeons eat insects. Fruit-eating pigeons do not typically drink water as most of their needs are met with the water in the fruit. However, seed-eating pigeons drink large quantities of water – up to 15% of their body weight daily. Pigeons that drink water have a unique method of drinking. Rather than scooping up water in their beaks, tilting their heads back, and allowing the water to run down their throats, pigeons are the only birds that immerse their beaks and suck in the water.

Rock pigeons are flock foragers, typically traveling less than 20 km (12.5 miles) from the roost to forage. Because foraging is a social behavior in pigeons, observational learning of foraging techniques is an effective way to transmit important skills to young birds. Pigeons are very effective social learners and they learn foraging skills through observation.

**Orientation, Navigation, and Homing.** For wild rock pigeons, daily forays usually cover relatively short distances, up to about 20 km. However, domestic and wild pigeons also have the ability to travel extremely long distances from strange places back to their home lofts or roosts. This ability has baffled breeders, racing enthusiasts, and scientists for decades. In fact, few topics in animal behavior have been studied so

persistently than the orientation, navigation, and homing abilities of pigeons (for an overview, see Johnston and Janiga 1995).

Johnston and Janiga (2001) point out several important limitations to these homing-related abilities. First, pigeons are not migratory birds; they remain in reasonable proximity to their home nests and within their home range all year round. Second, pigeons do not fly at night; they prefer to sleep. As such, they are insensitive to night sky information that is important for the migration of other birds. Instead, the unique orientation and navigational abilities of pigeons appear to be employed in the process of homing long distances and in unfamiliar landscapes. Mehlhorn and Rehkämper (2009) provide an overview of homing in the pigeon.

*Physiology of Homing.* Homing involves good vision, good olfaction, and a biological/neurological compass. In terms of physiology, extensive research has identified several key physiological organs and processes that contribute to successful homing, including iron-sensitive (Fe) magneto receptors in the beak, the trigeminal nerve, and the hippocampus.

*Sources of Homing Information.* Putative sources of homing-relevant information include geomagnetic fields, a sun compass, odors, and landmarks (see Fig. 9). Additionally, individual motivation (e.g., mate separation) and previous homing experience may influence return speed or return success. Furthermore, these systems

may work together, individually, or in redundant or overlapping subsets to allow birds to return home. Investigations, both laboratory- and field-based, have attempted to isolate and identify the relative contributions of each of these information sources.

*Geomagnetics.* Sensitivity to the earth's magnetic fields is implicated by the presence of magnetite-sensitive structures located in the upper beak of homing pigeons (Wiltschko et al. 2010). Research efforts to test this hypothesis typically attempt to disrupt the magnetic information being received by these structures or rely on naturally occurring anomalies in geomagnetic fields. Keeton (1971, cited in Mehlhorn and Rehkämper 2009) glued bar magnets to the backs of pigeons and then released them up to 50 km from their home roosts on sunny days. The magnets disrupted and slowed the return of the experimental birds (both naïve and experienced homers) compared to controls. Visalberghi and Alleva (1979, cited in Walcott 1996) attached Helmholtz coils to pigeons' heads and released them on sunny days. The result was a disruption in homing behavior suggesting that pigeons cannot (or do not) shift easily between a magnetic compass and a sun-based compass in order to find their way home.

*A Sun Compass.* When homing pigeons use the sun as a reference point, they must take their location and the sun's movement across the sky into consideration. Therefore, any sun-based

#### Pigeon (*Columbidae*),

**Fig. 9** Diagram of the putative contributors to successful homing. (From Lipp 1996, cited in Mehlhorn and Rehkämper 2009). To return from the release site to home (marked with a circle), pigeons may employ the use of a sun compass, a geomagnetic gradient, landmarks, and/or scents. Note also that motivation, experience, and environmental conditions are thought to play a role as well

compass must reflect sensitivity to solar East-West travel, seasonality, and time of day, as well as location. As yet, there is not a thorough understanding of how this is accomplished, but research on the sun compass goes back to the 1960s and 1970s. Most of the sun compass research involves clock-shifting pigeons by several hours, and then releasing them at a distance and watching changes in their compass bearings as they disappear over the horizon. A variety of contributing factors to successful sun compass use have been investigated, including (a) polarized light, (b) hippocampal lesions, and (c) the sun's azimuth. A sample of investigations exemplifies these investigative approaches.

(a) *Polarized Light*. The assumption that excellent vision is necessary for timely and accurate homing is flawed as some pigeons fitted with opaque goggles still find their way back to the loft. So while clear vision may or may not be critical for homing, light does appear to be important – particularly polarized light. Phillips and Waldvogel (1988) described how deflector loft housing redirects light and wind through a pigeon loft in a clockwise or counterclockwise manner. Deflectors are used to increase ventilation, decrease CO<sub>2</sub> buildup, increase light inside the loft, and manage loft temperatures in the summer. Phillips and Waldvogel noted that birds housed in deflector lofts that are released in the summer show a release site departure bias that matches the deflection in the home loft. Although initially used as evidence of olfactory cue effects on homing, they proposed that light deflection from these panels can also influence pigeons' vanishing bearings upon release from a distant site. Using two different deflector panels, the directionality of light and wind could be differentially controlled. Standard deflector panels rotate light and deflect wind such that both enter the loft from the same direction. Their experimental panels reversed light cues relative to wind flow. In this condition, light cues were rotated in a clockwise direction, while wind flow was rotated in a

counterclockwise direction. They also measured light polarization under the two deflector conditions. They found that in the standard deflector arrangement, the "band of maximized polarized light" (BMP) was consistent with natural light across the summer. However, with the experimental deflectors, the BMP is greatly altered relative to natural light. Behaviorally, there were differences too. Results showed that early in the summer, birds from the standard loft with typical deflector panels showed an average + 39° homing deflection upon release, whereas birds from the loft with the experimental panels showed an average – 19° deflection. By the end of August, the two groups' homing deflections had converged. But the findings suggest that an important part of a sun compass system is derived from polarized light, particularly in the early part of summer. The evidence suggests an important role for light polarization in the use of a sun compass for pigeons.

(b) *Hippocampal Lesions*. In a laboratory investigation, Bingman and Jones (1994) provided access to the daytime sky to help pigeons find food. Prior to training, the experimental birds' hippocampus was surgically lesioned. Control pigeons underwent a similar lesioning of the caudal neostriatum (a similar structure not used for orienting or navigating). A 1-meter-diameter, eight-sided, circular, testing arena had a clear top and holes in each of the eight walls for food cups. Cups were blinded to prevent visual cues from outside the arena. The testing apparatus was outdoors. The pigeons could see the sky through the roof of the arena. The birds were trained to eat from these cups. For each pigeon, food was always presented in the cup corresponding to a specific compass direction (East, West, or South). During testing, each bird was released in the center of the arena and allowed to explore the cup holes until it found food. Observers recorded where the birds' sequential choices occurred. Although all birds learned to explore and eat from the cups, the hippocampal-lesioned pigeons never learned

to find the food on the first try. Control pigeons learned the task quickly. Following a 6-h clock-shifting procedure, the control birds showed a 90° shift in their cup choices, as predicted. The hippocampal-lesioned birds were not tested in this condition because they had failed to learn the task initially. Together the hippocampal-lesioned and control birds' data provided strong evidence that (1) pigeons do use a sun compass and (2) the hippocampus plays a critical role in effective sun compass use for food finding.

- (c) *Sun's Azimuth*. Wiltschko et al. (2000) note that homing pigeons that use a sun compass must keep track of the differential movement of the sun throughout the day. This is not a simple task as the sun's path does not follow a simple algorithmic rule. The mathematical relationship between the vertical position of the sun over the horizon (i.e., azimuth) relative to its rate of travel from East to West is not linear. Immediately before sunrise and before sunset, the sun's altitude changes rapidly (but its azimuth does not). Throughout the day that relationship reverses. In the morning, the sun moves *up into the sky* quickly, but *less so across* the sky. Similarly around midday, the azimuth (e.g., travel across the sky) changes rapidly, but the sun's altitude changes little. Interpretation of this information requires sophisticated biology and cognition on the part of the pigeon, if it is to use the sun as a reference point. Wiltschko et al. (2000) clock-shifted birds by keeping them in a light-tight room in which automatic day/night cycles were shift back 4 h for at least 5 days. The shifted photoperiods began 4 h prior to natural sunrise and ended 4 h before natural sunset. Control birds were kept in a similar room with a window allowing for natural sunrise and sunset. The laboratory was approximately 25 km from their home lofts. Birds in both groups were released on sunny days, 1 h after their "sunrise" or 1 h before their "sunset," and vanishing points were recorded within 5°. Deflection of the vanishing points of the experimental birds was compared to that of the control birds. The results showed that the

clock-shifted birds' vanishing points also shifted in a manner consistent with the artificial sun's azimuth and travel rates across the sky. It appears that homing pigeons have sophisticated internal representations of the sun's curvilinear path that makes the use of a sun compass highly effective for homing.

*Landmarks*. Pigeons are remarkably loyal to navigation routes, at least when traveling short to moderate distances. Within familiar local territory, environmental objects and/or scents provide straight-forward sources of information. In the spatial memory literature, these objects are categorized into three groups that provide different kinds of information: beacons, landmarks, and environmental geometry (see Domjan 2015). Beacons are cues located at the goal. In the case of homing pigeons, a beacon might be the sight or scent of the home loft. Once detected, they can fly directly to the goal. A landmark is a distinctive feature that has a reliably fixed, physical relationship to the goal. A tall tree in close proximity to the home loft would be obvious examples of homing landmarks. The geometry of the environment can serve as a cue for narrowing in on a goal. A bird might learn that the home loft is located between a specific road and the highway. But how complex can landmark- > goal relationships become?

Blaisdell and Cook (2005) trained laboratory pigeons to find a food cup that was consistently presented between two landmarks (a red wooden L and a blue wooden T) on a 4 × 4 grid of no-food cups. All cups were filled with gravel; only the target had food buried in the cup. Odor cues were tested and ruled out as a viable cue. Within ten sessions, pigeons were choosing the correct cup on their first attempt. The introduction of distractors (tall PVC tubes painted to match the landmarks) briefly disrupted performance. But the birds' choices quickly came under control of the shapes and locations of the landmarks (and not based on color).

In a second set of training trials, only one reliable landmark, the blue T, was used, and its fixed relationship to the food cup was changed from the first training. Distractors were randomly

placed but never in the positions previous held by landmarks. Performance declined when the landmark- > goal relationship changed, but across trials, performance again improved. By the last session, birds averaged 1.8 choices to find the food.

In final integration tests, the blue T was replaced with the red L. The landmark- > goal relationship was the same as the previous set of trials (which was not consistent with the L's original position). The pigeons responded in a manner that suggests that they were able to integrate information from the two different training sessions to compute a new landmark- > goal spatial relationship. The results imply that pigeons can enlarge their spatial map by cognitively linking common elements with distinctive histories.

**Odors.** It is generally assumed that homing pigeons do utilize odor when homing. Much of the olfaction research had relied on one of two methods: (1) eliminating odors surgically or by blocking the nostrils to create "anosmic pigeons" or (2) experimentally manipulating odors at the home loft, during transport, or at the release site. Evidence from the distant release of anosmic pigeons, and with birds who have either been denied odors, or exposed to experimental odors, shows that their orientation and navigational abilities are compromised by odor manipulations. Despite concerns regarding possible behavioral side effects of the more invasive methods, the evidence remains compelling. However, when releasing at sites close to the home loft, anosmic pigeons simply fly home, suggesting that they are relying on redundant systems for local homing (such as familiar landmarks).

### Multimodal Methods and Redundancy

Throughout the history of homing research, the specter of a system with redundancy became simultaneously compelling and problematic. Homing appears to be part genetics/physiology, part multimodal learning, and part spatial mapping. Numerous theories of multi-system coordination or system redundancy have been proposed (Mehlhorn and Rehkämper 2009; Walcott 1996, 2005; Wallraff 1996). An integrated theory of homing is clearly needed to resolve and

synthesize the evidence from such a broad range of methods and theories (Wiltschko and Wiltschko 1994).

## Pigeons in the Laboratory

Professor B. F. Skinner began working with pigeons in the 1940s and published the first paper that documented the use of pigeons in the psychological laboratory: *Superstition in the Skinner* (1941). Long-lived and well adapted to captivity, pigeons quickly became a popular laboratory subject for the experimental analysis of behavior principles. In 1948, Dr. Skinner opened the Harvard Pigeon Lab (see Fig. 10), which remained in operation, contributing valuable operant conditioning research by exploring and explaining instrumental behavior, until it closed in 1998 (see ► "B.F. Skinner"). Since then, pigeons have become one of the two most common animal subjects in psychological laboratories for over five decades, along with the laboratory rat (*Rattus norvegicus*). Much of the laboratory research with pigeons fits into three main categories: (1) operant conditioning, (2) pigeon cognition, and (3) orientation and navigation.

**Operant Conditioning.** As a method of studying the determinants of behavior, operant conditioning became a dominant force within psychology in the mid-twentieth century. Because of their adaptability to captivity, their excellent perceptual abilities, and their longevity, pigeons quickly became the mainstay species for experimental investigations that focused on the fundamental principles of behavior, including acquisition of behavior, schedules of reinforcement, extinction, stimulus control, discrimination and generalization, and punishment. A truly comprehensive review of the research involving pigeons in the operant laboratory is beyond the scope of this summary. For an overview of the early research and fundamentals of behavior principles, see Domjan (2015). Of particular interest here is the role pigeons have played in the study of highly complex behaviors such as stimulus equivalence (aka derived or emergent relations between stimuli) and response variability as an operant.

**Pigeon (*Columbidae*),**

**Fig. 10** Dr. B. F. Skinner in the pigeon lab located in the basement of Memorial Hall at Harvard University. (Photograph of Dr. B. F. Skinner in the Harvard pigeon lab)

Such studies highlight the noteworthy cognitive ability of pigeons.

***Stimulus Equivalence (Derived Relations).***

Stimulus equivalence is a behavioral phenomenon in which two or more stimuli elicit the same response without having to be trained. It is an emergent phenomenon that was long thought to occur only in humans with language. More specifically, equivalence was said to occur when three specific criteria had been met. These criteria were based on a mathematical definition of equivalence that includes symmetry, reflexivity, and transitivity. Reflexivity (aka sameness) is achieved when a subject can match an item or object to itself (e.g.,  $A = A$ ,  $B = B$ ,  $C = C$ , etc.).

Symmetry is achieved when the relationship between two objects or items is bidirectional (e.g.,  $A = B$  and  $B = A$ ). Transitivity is achieved when relationships exist between several object pairs (e.g., if  $A = B$  and  $B = C$ , then  $A = C$ ). In psychological research, transitivity is often a test of emergent stimulus equivalence, aka a derived relationship. According to Sidman and Tailby (1982, cited in Vaughan 1988), true stimulus equivalence requires all three components.

Over 40 years ago, the formation of functional concepts of trees, bodies of water, and specific people by pigeons was demonstrated when birds were able to generalize their discriminations to never before seen pictures of trees (Herrnstein et al. 1976). But, stimulus equivalence by non-human animals (pigeons) was first claimed by

Vaughan in 1988. Pigeons were reinforced for responding to a set of 20 out of 40 slides of trees over 15 sessions. Responses to the remaining slides were not reinforced. A series of reversals were then repeated for a total of more than 800 sessions. On session 813, a new set of distinct slides of trees were introduced and tested. The results showed that the pigeons had indeed formed equivalence classes. Vaughan referred to a functional similarity to stimulus equivalence because formal tests of the three equivalence requirements were not conducted, raising concerns by equivalence purists. Vaughan (1989) argued for abandonment of the artificial use of mathematical equivalence in favor of a more function definition of equivalence. The idea that nonhuman, nonverbal animals like pigeons could develop equivalence relations provoked controversy and debate (Hayes 1989; Vaughan 1989). Although the debate has not been resolved, limited success with functional equivalence has since been demonstrated in non-human species including pigeons, primates, and sea lions. But strong, reliable experimental evidence of equivalence of any kind across non-human animals continues to prove illusive. However, the original equivalence work with pigeons (Vaughan 1988) rekindled serious interest in avian cognition.

***Response Variability as an Operant.*** Response variability has been viewed conceptually as critically important for processes such as shaping and for schedules of reinforcement. In many ways,

response variability has long been viewed as a key component for Skinner's (1981) selection by consequences explanation of operant conditioning. He considered it an operant/behavioral analog to the individual genetic variation necessary for successful natural selection (Skinner 1981). But for decades, it remained an assumption, and nothing more.

In 1985, Page and Neuringer explicitly asked whether random response patterns could be treated as an operant – whether it was a “reinforceable” (sic) behavior. Pigeons were positively reinforced on every trial if their pattern of 8 left and right key pecks differed from their pattern of responding on previous  $n$  trials. They called this  $n$ -trial requirement a LAG. Over a series of six experiments, Page and Neuringer (1985) systematically increased the LAG requirement to prevent repeated patterns of eight responses over one, two, or three trials, to LAGs of 25 and even LAG 50. In many conditions, (including LAG 25) the birds' response variability approximated a computer random numbers generator. Never before had behavioral randomness come under stimulus control in this way.

Research on response variability has continued for over 30 years (for a review, see de Souza Barba 2012), including evidence from other species. Although not unique to columbids, or even birds, it is important to note the key role pigeons played in the discovery and investigation of the determinants of response variability.

### Pigeon Cognition

In 2001, Robert J. Cook – perhaps the foremost expert on pigeon visual cognition – edited an online volume, *Avian Visual Cognition*, in which he invited 31 of the world's best-known experimental psychologists and animal behaviorists to contribute to a comprehensive summary of the current knowledge of comparative avian cognition. See ► “Visual Perception”. It is important to begin any discussion of pigeon cognition by stating that the pigeon brain is more closely related to the dinosaur brain and it is only about 1/1000th the size of a human brain. As such, comparative research provides insight into both the cognitive abilities of pigeons (and other birds),

but also into the evolutionary context for the development of bird and mammalian (i.e., human) perceptual cognition.

### Pigeon Visual Perception

Avian perception is highly developed and organized around vision. Flight plays a central role in foraging, predatory avoidance, mate and nest identification, and homing. Therefore, the role of visual information and processing in a bird's life, and how it diverges and converges with human visual cognition, is key to a clear picture of avian cognitive abilities related to texture perception, perceptual organization, and object and motion perception. The method most commonly used is a visual detection task in which an array of images are presented and subjects are timed to see how long it takes to detect a specific image in the array (see ► “Visual Detection Task”).

*Feature perception.* Treisman and Gelade (1980, cited in Cook 2001) showed that humans require several visual passes over a complex stimulus in order to identify a complex target with both color and shape cues. Elements that are inconsistent with the larger array tend to “pop out” from organizationally uniform backgrounds, but this requires simultaneous and pre-attentive processing of the various features (called feature integration theory). Cook, Cavoto, and Cavoto (1996, cited in Cook 2001) tested whether pigeons in operant chambers viewing complex visual displays would exhibit similar visual strategies compared to humans. Using two- and three-dimensional stimuli, Cook et al. highlighted several similarities between the birds and humans. Pigeons and humans vary their search strategies depending on how the stimuli are organized. For example, as the dimensional differences increase, so too did reaction times for both birds and people. Also, distractors similarly hurt performance. Adding irrelevant dimensional information had no effect on avian or human reactions times, and both showed improvements from combining redundant and relevant information. The results suggest that early visual processing for birds and humans converge with regard to globally relevant information. Additional findings suggested important differences. For example, pigeons are

**Pigeon (*Columbidae*),****Fig. 11** Global/local training and testing stimuli from Cavoto and Cook (2001, cited in Cook 2001)

faster at detecting global information differences (100 ms minimal thresholds) compared with humans (150 ms).

*Global/local hierarchical organization.* Humans generally tend to prioritize larger, more global information over local (e.g., component/detailed) information, a phenomenon known as the global precedence effect (Navon 1977, cited in Cook 2001). Early work related to global versus local control of perception (Cook and Tauro 1999, cited in Cook 2001) led to feature-based perceptual models of behavior control (Huber, 2001, cited in Cook 2001). However, additional evidence suggests that it is not just the global or local features that matter but the relationships between global and local features that influence their discriminative abilities. For example, humans attend to words over letters, and entire letters over the shapes used to configure letters. This tendency reflects our acquired reliance on language and reading.

Cavoto and Cook (2001, cited in Cook 2001) provided similar base training for pigeons by presenting them with four letters (TNXH) constructed in four different ways: (a) *global-relevant* (e.g., T, N, X, and H constructed with tiny Os), (b) *local-relevant* (e.g., T constructed with tiny Ts), (c) *global-equivalent* (plain, large font letters), and (d) *local equivalent* (plain, small font letters).

Figure 11 shows the stimuli used in Cavoto and Cook's (2001, cited in Cook 2001) study. For global-relevant stimuli (line 1), only the larger letters were deemed relevant; the smaller "O"s used to construct the larger letters were deemed irrelevant. For local-relevant stimuli (line 2), only the smaller letters used to construct the larger "O"s were deemed relevant; again the "O"s were deemed irrelevant. The larger and small, solid letters presented global and local equivalents of the compound stimuli. Within a trial, birds saw stimuli from one or the other (global or local) organizational arrangement, but across trial both types were presented equally often. Using a simultaneous matching-to-sample procedure, birds were presented with one of the four configurations in random locations on a computer screen. Next, four (solid) letter choices were presented.

Testing to see the order in which the birds matched the global and local stimuli to the eight different equivalents, Cook (2001) highlighted two major findings. First, the birds learned to discriminate the local-relevant stimuli significantly faster than the global-relevant stimuli. Second, accuracy for the local-relevant stimuli was significantly better than for the global-relevant stimuli. These findings were consistent during acquisition and with extended training. They then tested generalization to a new letter S (both globally and locally relevant). The birds

successfully showed transfer of training with the new letter (despite initial difficulty with the global-relevant stimulus). These data contrast with the typically stronger global advantage found in humans. Understanding proximate and ultimate causes of the difference between animals and humans is the next step and should consider possible evolutionary causes as well as neuroanatomical correlates.

### Foraging and Cognition

Pigeons are social animals and flock foragers. They frequently search for food hidden in a background of inedible objects and items; as such, observational learning is a useful way to transmit effective foraging techniques skills to novice foragers (Blough 2001).

*Observation Learning of Foraging Techniques.* Pigeons are effective social learners. They can learn new behaviors through observation and imitation. However, the development of a scrounging approach (e.g., parasitizing other more effective foragers) is a risk. While individual pigeons in a flock use both foraging and scrounging methods, they do so flexibly such that most birds learn the foraging techniques for themselves.

In a laboratory-based investigation of observational learning in pigeons, Giraldeau and Lefebvre (1987) asked if scrounging alone would be sufficient for learning how to forage (see ► [“Imitation”](#)). Tutor birds were trained to obtain food by pecking at a stick that released seeds. Observers were then allowed to watch the tutors work to earn the food. Seeds dropped either toward the observers (aka scroungers) or toward the tutors themselves making the other birds simply observers of the pecking strategy. Observer birds from both conditions were then tested to see whether they had learned to peck at the stick to release the seeds. The simple observers learned to peck at the sticks for themselves, but the scrounger birds (who had received the food) failed to learn the foraging strategy. Giraldeau and Templeton (1991) also note that food producers often consume large shares of the food they find, leaving less for scroungers. So although scrounging may be a valuable strategy

on occasion, it is not effective as the sole foraging strategy because it leaves the learner at risk of food shortage.

*Searching.* In a review of her laboratory investigations, Blough (2001) compared various foraging-related cognitive processes in pigeons to human detection tests. For pigeons and humans, target-to-background contrast facilitates target identification (Treisman and Gelade 1980, cited in Cook 2001). For this reason, evolution has favored crypsis among prey species. Pigeons, like people, search more rapidly for targets that are expected, and when there are fewer distractors, and when there is less similarity between distractors and targets. Target-distractor differences mean a faster search resolution for both species. However, not all features facilitate search efficacy for both humans and pigeons. Humans switch from a serial search to a parallel strategy when changing from distinctly and randomly arranged distractors to distractors that are distinguished by a line or a gap (Treisman and Gormican 1988, cited in Blough 2001). Pigeons did not show that same shift in search patterns – what seem like natural groupings to us don’t help pigeons much at all.

*Memory for Targets.* Memory also plays an important role in the search process, particularly with respect to our memory for acceptable foods or targets. Pigeons (like people) are good at remembering which pictures that they have seen previously or not from a large set (Vaughan and Greene, cited in Blough 2001), and they can learn a “set of targets” which can then be imbedded in a display of previously unseen distractors. Over a series of experiments (Blough 1984, cited in Blough 2001; Vreven and Blough 1998), pigeons were tested with only one target or with several targets in a display of distractors. If a parallel search pattern were being employed, there should be no differences in reaction times. Despite early failures, sizeable differences ultimately emerged during preliminary tests, but performances converged during extended testing, consistent with other changes produced by extended practice. These findings were consistent with other changes produced by extended practice.

## Pinniped Cognition

Mysteria M. Samuelson  
Animal Behavior Core, Department of  
Comparative Medicine, The University of  
Nebraska Medical Center, Omaha, NE, USA

### Introduction

Pinnipeds are amphibious caniform carnivores and can be divided into three families including otariidae (eared seals, including fur seals and sea lions), phocidae (true seals), and odobenidae (walruses; Arnason et al. 2006). Unique physiological and cognitive capabilities have evolved in these species due to their ability to compete in both aquatic and terrestrial environments. For the purposes of this chapter, cognition was considered to include “higher-level processes involved in storing, editing, and integrating sensory information such as memory, perception, and learning” (Deecke 2006, p. 461). This chapter outlines the behavior and cognition of wild

pinnipeds, as well as important laboratory studies. The information presented by these studies has not only provided a window into the pinniped mind, but also revealed new strategies for the management of both wild pinnipeds and those under managed care.

An animal’s ability or inability to perceive specific stimuli, known as an *umwelt*, is limited by species-specific sensory capabilities, thus affecting their behavior and cognition in nearly every context (see Partan and Marler 2002). Because cognition is so greatly affected by an animal’s ability to perceive environmental stimuli, this chapter will focus strongly on pinniped sensory cognition and the implications of pinniped’s sensory capabilities.

### Wild Pinniped Cognition and Communication

With the exception of some phocids, most pinniped species mate and give birth on land. This reliance on land or ice flows for reproduction has allowed scientists to evaluate these species’ reproductive behavior in close detail. For example, many of these species, such as California sea lions (*Zalophus californianus*) and northern elephant seals (*Mirounga angustirostris*), are highly gregarious and congregate in large rookeries (Cassini 1999). In order to facilitate the reunification of mothers and pups within these crowded rookery environments, individual recognition is necessary. Acoustic recognition has been studied extensively in a variety of wild pinnipeds (see Deecke 2006 for a review) and has been observed in otariids (Pitcher et al. 2012), grey seals (*Halichoerus grypus*; McCulloch and Boness 2000), northern elephant seals (Petrinovich 1974), and walrus (*Odobenus rosmarus rosmarus*; Charrier et al. 2013). Playback experiments have been useful in evaluating the function of pinniped vocalizations and their behavioral and psychophysiological responses. This approach has allowed researchers to examine the higher-level processes of pinnipeds in the wild, through employing noninvasive techniques. These capabilities include not only individual

acoustic perception, but also the ability of pinnipeds to account for gradual changes in acoustic stimuli, such as in a pup's vocal signature as it ages (see Deecke 2006 for a discussion). The use of playback experiments has not been limited to behavioral and acoustic assessments alone. Deutsch et al. (1990) utilized recordings of aggressive male vocalizations to lure male northern elephant seals to cross a weighing platform, in order to evaluate changes in body weight throughout the breeding season. In this study, researchers were able to employ an understanding of pinniped cognition to obtain physiological measurements in a noninvasive manner.

Pinnipeds produce a wide range of vocalizations, which has warranted extensive evaluation to determine their structure and function (see Schusterman and Van Parijs 2003 for a brief review). These vocalizations are thought to be social in nature, as they do not use sound for the purposes of navigation or foraging as cetaceans do. Therefore, research aimed at understanding communication has largely focused on the social contexts in which these vocalizations occur (Schusterman 2008). In terrestrially breeding species, where animals congregate in large rookeries, calls are typically both loud and repetitive in nature, making them ideal for information transfer in loud rookery environments (Schusterman and Van Parijs 2003). Alternately aquatic breeding phocids, which mate in less concentrated areas where information transfer is less difficult, produce more elaborate mating vocalizations (Schusterman 2008). When examined through the lens of Information Transfer Theory, it is clear these differences in species' communication styles appear to be adaptive in response to a decrease in competition in less-crowded aquatic environments (Schusterman and Van Parijs 2003).

Both research in the wild and in under controlled laboratory settings has contributed greatly to our understanding of pinniped vocal learning. While these adaptive strategies can be observed in the wild and in laboratory studies, opportunistic studies of animals living in professionally managed care has also been helpful in adding to our understanding of vocal learning in pinnipeds. Experimental evidence has demonstrated vocal

learning in phocids otariids and walrus. In these studies, animals were trained to produce natural vocalizations in response to a discriminative stimulus, regardless of context. However, walrus and phocids have also been demonstrated to have some ability to produce novel vocalizations in response to a discriminative stimulus. While isolation experiments have not been conducted in pinnipeds, for ethical reasons, it has been observed that when raised in the absence of conspecifics, pinnipeds appear not to develop a species-typical vocal repertoire. This is even true in the case of sex-specific vocalizations. That is, males may not develop the full vocal repertoire typical to their wild counterparts, when reared with only female conspecifics (see Reichmuth and Casey 2014 for a review).

## Learning and Long-Term Memory

In addition to vocal learning, capabilities such as discrimination and concept learning have likewise been evaluated. Reichmuth, Kastak, and Schusterman (2002) demonstrated that not only are pinnipeds capable of performing these tasks, but they are also capable of committing these tasks to their long-term memory. In this study, a sea lion who had received long-term exposure to both discrimination and concept-learning tasks was re-tested after a delay. The results of this evaluation demonstrated that the animal (a female California sea lion) showed no reduction in performance on associative concept, equivalence classification, and match-to-sample tasks after a 1-year delay and one matching task after a 10-year delay – even when presented with novel stimuli.

## Pinniped Cognition and Sensory Biology

The field of pinniped cognition and sensory biology has benefited greatly from laboratory-based research. This work examining pinniped cognition under controlled settings has not only increased our understanding of pinniped communication (e.g., Schusterman and Van Parijs 2003), but also our knowledge of brain structure and

function (e.g., Böye et al. 2005; Cook et al. 2015). By extension, this research has led to an understanding of not only the ability of pinnipeds to learn, but also their hearing, visual (see Schusterman 1981), and olfactory capabilities (Laska et al. 2010). Laska et al. (2010) found that South African fur seals (*Arctocephalus pusillus*) can discriminate between 24 of the 25 aliphatic odorants, presumed to be present in the marine environment, which were presented in a simple discrimination task. This ability to discriminate between scents suggests that scent is likely evolutionarily salient for these species. Studies of this nature are critical in that they not only reveal the species' Umwelt, or stimuli which the animals are capable of detecting, but also reveal the animal's cognitive ability to differentiate between these stimuli.

## Threat Perception

Acoustic playbacks have been applied to the management of wild pinnipeds, through the use of aversive stimuli (i.e., killer whale vocalizations) to deter the depredation of managed fisheries (see Deecke 2006 for a review). Unfortunately, these attempts have yielded only temporary behavioral change. The transient effect of these interventions can likely be explained by examining the cognitive mechanisms and evolutionary pressures involved in threat assessments (Schakner and Blumstein 2013). For example, Fanselow and Lester (1988) hypothesized that prey species evaluate threatening environmental stimuli, such as predator vocalizations on a continuum, called the *Predatory Imminence Continuum*. This continuum suggests that if the individual perceives that a stimulus indicates zero threat of predation, they are at the preferred point on the continuum and they will continue engaging in nonaversive behaviors (i.e., foraging, nursing, etc.). However, if the animal perceives that a threat is imminent, they will likely engage in energetically expensive, aversive behaviors (i.e., increase vigilance, decrease foraging, etc.). This theory assumes that evolution would select for an adaptive strategy in which animals would engage in aversive

behaviors until such time as the stimulus, such as killer whale calls, is either evaded entirely or determined to not to be a threat – allowing them to return to the preferred point on the continuum. Drawing on this knowledge and the growing literature on pinniped acoustic thresholds, managers have also introduced intense acoustic stimuli designed to cause pain if the animal approached the signal source, in order to deter depredation (see Würsig and Gailey 2002 for a review). This approach has achieved minimal success due to the ability of pinnipeds to engage in temporary acoustic threshold shifts, or the temporary elevation of auditory thresholds following overstimulation (e.g., Kastak and Schusterman 1996), in which animals are able to cope with loud noises long enough to continue foraging – or permanently, depending upon length of exposure to the stimulus and the intensity of the stimulus. Thus, the animal elects to expose itself to the unpleasant sound stimulus, once it is determined not to be a threat. This cognitive perspective has allowed for researchers and managers to not only evaluate pinniped threat perception, but also to design aversive interventions such as acoustic deterrents.

## Theory of Mind

The ability to recognize oneself in a mirror is considered evidence that one is aware of its own existence. Delfour and Marten (2001) evaluated California sea lion reactions to a mirror in comparison to killer whales (*Orcinus orca*) and false killer whales (*Pseudorca crassidens*). They found that pinnipeds lacked the necessary contingency checking behavior to be considered to possess mirror self-recognition. However, Genty and Roeder (2006) demonstrated that California sea lions performed better than nonhuman primates on a reverse-reward contingency task. In this task, subjects were presented with two options: a selection including one fish and a second selection with five fish. If the individuals selected the first option (one fish), they would receive the second (five fish). Alternately, if they selected the second option (five fish), they would receive the first (one fish). Despite a demonstrated initial impulse

to select the higher quantity of fish, three out of the four animals quickly learned the rules of the trials. The subjects' successful performance on this task is indicative of a higher level of self-control than most nonhuman primates. In humans, only children aged 4 years and older, who present with some theory of mind, show similar self-control capabilities. These enhanced capabilities may have evolved in response to the dynamic foraging environment pinnipeds experience in the wild (see Genty and Roeder 2006 for a discussion).

Alternately Shapiro et al. (2004) evaluated gray seal's ability to follow an experimenter-given point. In this study, the animal was able to follow various points given from central and lateral positions. However, the animal was not able to follow points which indicated an object located behind the animal. Thus, it was concluded that the seal was likely only able to follow points by employing signal generalization as a result of past experience with operant conditioning, rather than a comprehension of the gesture itself. The ability to understand gestures, such as pointing, has been suggested to indicate that the animal is able to engage in visual perspective taking, which is indicative of theory of mind and some level of self-awareness (see Shapiro et al. 2004 for a discussion).

When compared with the literature on cetaceans and nonhuman primates, there have been relatively few studies examining the theory of mind or self-awareness in pinnipeds. More research will need to be done in order to conclusively address questions associated with the abilities of pinnipeds to engage in these concepts.

## Cognitive Abnormalities in the Wild and Under Human Care

Wild pinnipeds are exposed to a variety of threats on an everyday basis, some of which can cause long- and short-term cognitive deficits leading to strandings and possibly death. Domoic acid is an excitatory neurotoxic amino acid produced by the algae *Pseudonitzschia*, which has been shown to cause damage to the hippocampus and hippocampal-thalamic brain networks in animals

that ingest it. This damage ultimately results in deficits in spatial cognition, which can interfere with foraging and navigation, in wild pinnipeds (Cook et al. 2015).

Abnormal behaviors may also arise as a result of insufficient environmental stimulation in animals under human care, requiring the constant evaluation of environmental enrichment protocols used to eliminate or reduce instances of stereotypical behavior. Numerous methods, and a combination of stimuli, have been found to reduce stereotypical behavior. These methods include: allowing animals to have more choice over their environment as well as introducing problem-solving devices and tasks (Clark 2013). Other methods, such as increasing environmental complexity through the introduction of novel stimuli, such as scents, has also been demonstrated to improve the welfare of pinnipeds under human care (Samuelson et al. 2016).

## Summary

Pinniped cognition has been the subject of intensive research for many years. The results of these studies have revealed a wealth of knowledge regarding not only the cognitive capabilities of these marine mammals, but also of their unique Umwelt with which guides their cognition. Advancements in our scientific understanding of pinniped hearing, vision, and scent capabilities have allowed researchers to investigate their communication, conservation, and the welfare of animals in human care.

## Pinniped Communication

Taryn Eaton  
Oakland University, Rochester, MI, USA

**Pinniped:** Pinnipeds are semiaquatic, carnivorous mammals comprised of 33 living species in three major families: phocids (true seals), otariids (sea lions and fur seals), and odobenids (walruses; Schusterman 2008).

**Communication:** A signal that provides information from a signaler to a receiver (Tyack and Miller 2002).

## Introduction

Pinnipeds are among the most vocal of all mammals, communicating in both water and air (Miller 1991; Schusterman et al. 2001). The sounds produced by pinnipeds are used almost exclusively for social communication, such as courtship and copulatory signaling, establishing and maintaining territories through agonistic signals, and mother-pup reunification (Winn and Schneider 1977; Van Opzeeland et al. 2008). A majority of the pinniped sounds that have been documented are within the range of human hearing (Dudzinski et al. 2009). Phocid calls are typically between 100 Hz and 15 kHz (Dudzinski et al. 2009). Airborne sounds produced by otariids range from 1 kHz to 4 kHz, while sounds produced in the water are slightly louder (Dudzinski et al. 2009). Odobenids produce low frequency sounds ranging from 500 Hz to 2 kHz (Dudzinski et al. 2009). The amount of vocal communication varies between species. Some pinniped species are almost silent, whereas others have large vocal repertoires consisting of calls characterized

as grunts, rasps, rattles, growls, warbles, trills, chirps, chugs, clicks, and whistles (Dudzinski et al. 2009). The amount and type of calls produced and used varies not only by species but by season, sex, age, and whether the animal is in the air or in the water (Dudzinski et al. 2009). Pinnipeds also communicate through non-acoustic signaling, such as visual displays, tactile communication, and chemical communication (Miller 1991). The following text will review the acoustic behavior of pinnipeds, as well as the forms of non-acoustic signaling used. Gaps of knowledge will be addressed with suggestions for directions of future research.

## Acoustic Behavior and Mating Strategies

The amount of vocalizations produced by pinnipeds is correlated with their mating system and whether mating occurs on land or underwater (Stirling and Thomas 2003). Of the pinnipeds, phocids tend to be more vocal under water, otariids on land, and odobenids in both media (Dudzinski et al. 2009). Pinnipeds that are seasonally monogamous, such as crabeater seals (*Lobodon carcinophagus*) and hooded seals (*Cystophora cristata*) have the least complex mating system, resulting in the simplest repertoire (with the fewest amount of different vocalizations; Stirling and Thomas 2003). In fact, crabeater seals only exhibit a single monotonous call which is thought to be used in short-range male-male competition when guarding a female (Van Opzeeland et al. 2008). Promiscuous pinniped species, in which males are not able to defend exclusive territories and both individual males and females likely mate with more than one seal, have been shown to have an intermediate number of vocalizations (Stirling and Thomas 2003). For example, leopard seals (*Hydrurga leptonyx*) exhibit 9–12 different vocalizations (depending on the region) that they use to establish short term, underwater territories and to attract females to mate with (Dudzinski et al. 2009). Polygamous pinnipeds, in which males defend underwater territories and have access to more than one female at

a time, have the most structured mating systems and, therefore, the greatest number of different vocalizations (Stirling and Thomas 2003). For instance Weddell seals (*Leptonychotes weddellii*) congregate in colonies of up to 100 females and pups, while males establish and defend territories beneath the fast ice and may mate with as many females that enter their territory (Dudzinski et al. 2009). These seals have been found to have an elaborate repertoire consisting of at least 34 distinct sounds, including trills, chugs, chirps, guttural glugs, and knocks (Dudzinski et al. 2009; Van Opzeeland et al. 2008).

When comparing species within each mating system described above, those that form the densest colonies during breeding have broader repertoires with a wider variety of sounds than those at the lowest densities (Van Opzeeland et al. 2008; Stirling and Thomas 2003). Moreover, the high density of animals within breeding colonies seems to favor the production of loud, harsh, repetitious calls (Schusterman 2008). Harp (*Pagophilus groenlandicus*) and Weddell seals, the phocid species that form the densest colonies, are particularly known for the diversity, high rate of occurrence, and amplitude of their calls (Stirling and Thomas 2003). Watkins and Schevill (1979) found that harp seals increase the volume and number of elements per call in response to higher calling rates by conspecifics (i.e., animals of the same species). Additionally, Atlantic walruses (*Odobenus rosmarus rosmarus*), which aggregate in colonies of 30–100 or more, make a large number of distinct vocalizations which are comprised of two main variations on a single-pulsed sound, a sharp relatively low-pitched “knock” and a higher-pitched “tap” given in different combinations (Stirling et al. 1987). In the vicinity of females and calves, male Atlantic walruses vocalize extensively underwater, making repeated, individually stereotyped calls made up of varying combinations of several hundred pulses (Stirling et al. 1987; Van Opzeeland et al. 2008). These vocalizations are loud and can readily be heard by humans standing on the ice (Stirling and Thomas 2003). The increase in volume and number of calls made in high density breeding colonies may help to mask the calls of competitors, while

at the same time, increase the probability of signal detection by others (Stirling and Thomas 2003).

As stated previously, some pinniped species establish and defend territories during mating (Stirling and Thomas 2003). Males of species that maintain territories have intense, complex, inter-male warning calls (Winn and Schneider 1977). Arguably, the most elaborate warning call may be the warbling song of the bearded seal (*Erignathus barbatus*; Winn and Schneider 1977). Additionally, male Weddell seals have 11 types of trills that they use exclusively in agonistic interactions while defending territories (Dudzinski et al. 2009). The territorial calls of otariids are of low frequency, pulsed, and typically accompanied with an elevated posture (Winn and Schneider 1977). The type of male territorial call used is related to motivational state (Winn and Schneider 1977). For instance, the snort produced by northern elephant seals (*Mirounga angustirostris*) is the lowest intensity threat sound produced by this species and is typically the first sound produced in agonistic interactions (Winn and Schneider 1977). The clap threat is of higher intensity and typically signals incipient attack (Winn and Schneider 1977). Similarly, Weddell seals use short, quiet trills as an initial warning to other males and long, loud trills to threaten attack (Dudzinski et al. 2009).

### Acoustic Behavior of Mother-Pup Pairs

In many mammals, including pinnipeds, mother and offspring can identify each other using a variety of sensory modalities (Charrier et al. 2009). Pinnipeds are nearsighted when out of water (Wartzok and Ketten 1999) and can only utilize olfactory cues to confirm recognition once mother and offspring come in contact (Stirling 1971). As visual and olfactory cues are less effective at long range, pinnipeds primarily use acoustic signals for individual recognition (Charrier et al. 2009). Vocal recognition between mothers and offspring is prevalent among pinnipeds; however, it is thought to be better developed in otariids (fur seals and sea lions) than in phocids (true seals; Khan et al. 2006). This difference may be due to

variances in maternal strategy (Insley et al. 2003). Otariids use a “foraging cycle strategy” characterized by a long period of offspring dependence, during which the mother alternates between hunting trips at sea with time on land nursing her pup (Bonner 1984). As a result, mothers must repeatedly relocate their pups throughout the course of lactation (Insley 1992). In contrast, many phocids use a “fasting strategy” in which mothers fast while nursing and continuously care for their pups (Insley 1992). Therefore, mothers and offspring have little need to find one another except when temporarily separated over short distances (Insley 1992). Regardless, females and pups of many phocid species regularly vocalize (Insley 1992).

Vocalizations made by nursing pairs have been termed pup attraction calls (made by mothers) and mother attraction calls (made by pups; Winn and Schneider 1977). Individual stereotypy in these calls is crucial for vocal recognition, as it enables individuals to differentiate between one another (Van Opzeeland et al. 2008). Thus, pup recognition by mothers using acoustic cues is only possible once pups begin to produce unique vocalizations (Khan et al. 2006). Similarly, mother recognition by pups is only possible once pups learn the unique vocalization of their mothers. This can take anywhere from 3 days, in the Steller sea lion (*Eumetopias jubatus*), to 2 months, in the New Zealand sea lion (*Phocarcos hookeri*; Winn and Schneider 1977). To date, the calls used between otariid mothers and pups exhibit individual stereotypy in all species that have been studied (Insley et al. 2003). In phocids, individual stereotypy in calls is much more variable between species. In many phocid species, mothers rarely vocalize to their pups and consequently, do not exhibit call stereotypy (Insley et al. 2003). However, evidence for individual stereotypy in pup calls has been found in colonial breeding phocid species, such as Weddell seals (Collins et al. 2005), grey seals (*Halichoerus grypus*; McCulloch and Boness 2000), harp seals (Van Opzeeland and Van Parijs 2004), and elephant seals (*Mirounga*; Bartholomew & Collias, 1962). Walrus calf vocalizations have also been found to be highly stereotyped

(Charrier et al. 2009). Individual vocal stereotypy has been correlated to individual recognition in many pinniped species, including Weddell seals (Collins et al. 2005), northern fur seals (*Callorhinus ursinus*; Insley 2001), and is well developed in many walrus species (Kibal'chich and Lisitsina 1979; Miller 1985). However, individual stereotypy in vocalizations does not always indicate individual recognition. For instance, McCulloch and Boness (2000) used playback experiments to test individual recognition of pups by mothers in two grey seal colonies in Canada. They found that grey seal females in the Sable Island colony were able to discriminate between the vocalizations of their own and unfamiliar pups, whereas females in the Isle of May grey seal colony were not able to make this discrimination. Additionally, sex differences have been found in some pinniped species in regard to mother-pup vocal recognition. Van Opzeeland et al. (In prep) found that vocalizations of female harp seal pups in the Greenland Sea population were significantly more individually stereotyped than males, biasing maternal recognition towards female pups. The amount of distinct information in both mother and pup calls, combined with visual and olfactory cues, seems to allow mother-pup pairs to recognize each other (Van Opzeeland et al. 2008).

## Non-Acoustic Signaling

Acoustic communication is the best known, and most studied, form of pinniped communication (Miller 1991). However, pinnipeds also use forms of non-acoustic communication, such as displays (i.e., visual signals). Visual displays can be simple, such as body postures, coloration, or sexually dimorphic features, or can be more elaborate, involving sequences of behavior (Dudzinski et al. 2009). Social, land breeding pinnipeds, including otariids and some phocids, have highly stereotyped and ritualized displays (Winn and Schneider 1977). Threat displays are a common part of territorial behavior in pinnipeds and often include acoustic elements (Winn and Schneider 1977). For example, the in water

territorial display of Weddell seals consists of an S-shaped posture with the chest forward and the hind flippers downward paired with loud trill and teeth chatter sounds (Dudzinski et al. 2009). Additionally, when approached on pack ice, Ross seals (*Omatophoca rossii*) assume a head-up posture, showing off the stripes on their chest, and open their mouths, showing their teeth, while making loud sounds (Dudzinski et al. 2009). Flipper waving has also been described as a low-intensity visual warning in grey, harp, and ringed seals (Winn and Schneider 1977). Submissive behavior has also been described in some otariids and in elephant seals (Winn and Schneider 1977). For instance, male southern elephant seals (*Mirounga leonina*) signal submission by deflating their proboscis (i.e., their elongated nose or snout), backing away, and uttering high-pitched whimpers (Winn and Schneider 1977). Visual displays are also used by female pinnipeds to signal estrus and solicit copulation. Female northern fur seals (*Callorhinus ursinus*) display an exaggerated walk when in estrus (Winn and Schneider 1977). Further, displays made by female Steller sea lions when in estrus may be crucial for inducing males to mount (Winn and Schneider 1977).

Visual displays are advantageous in close-range communication among pinnipeds and, because of close proximity, visual displays may turn into tactile signals (Dudzinski et al. 2009). Tactile communication is an important element of pinniped mating (Miller 1991). Males of many pinniped species make extensive contact with females during courtship. For example, male crabeater seals maintain almost constant physical contact when courting a female (Miller 1991). This contact includes resting their head on the female's side, lying with their back touching the female, and lying with their chest over the female's back and their fore flipper extended over her side (Miller 1991). Male and female southern sea lions (*Otaria flavescens*), Australian fur seals (*Arctocephalus pusillus*), and Steller sea lions also use tactile communication during courtship, often caressing one another on the front and sides of the neck and rubbing their mouths together (Miller 1991). Steller sea lions and harbor seals (*Phoca vitulina*) also engage in aquatic

social rolling behavior in which males and females roll around each other while maintaining physical contact (Miller 1991). Additionally, female grey seals may initiate copulation by nuzzling a male and female fur seals that are ready to mate have been shown to rub heads and noses with males, as well as rub and nip at a male's neck and jaws (Winn and Schneider 1977). Tactile communication is also important between mother-pup pairs. Nuzzling, which aids in individual recognition, is common between females and pups of all pinniped species (Miller 1991). Furthermore, many otariid mothers have been shown to mouth and lift their newborn pups (Miller 1991), and female New Zealand fur seals (*Arctocephalus forsteri*) often press themselves on top of their newborn pups (McNab and Crawley 1975). Lastly, tactile communication may be used to solicit play. McNab and Crawley (1975) noted that New Zealand fur seals pups solicited play from their mothers by passing their mother's whiskers through their mouth and over their head and nose and by gently biting their mother's nose, mouth, and upper neck. Mothers responded by gently biting back and ended play by pushing their pup away and moving their head away (McNab and Crawley 1975). Juvenile grey seals also solicit play using tactile communication, often by laying their head over the back of another individual (Miller 1991).

Along with visual displays and tactile communication, pinnipeds often use forms of chemical communication, olfaction in particular. Males of many pinniped species, including ringed seals (*Pusa hispida*) and harp seals, exude strong, musky odors that may be used in territorial marking or to attract a female (Winn and Schneider 1977). Further, olfaction is used by males of many pinnipeds to investigate the reproductive state of females. For example, male New Zealand fur seals smell rocks used by females, as well as the females themselves, to determine if a female is ready to accept a mate (Winn and Schneider 1977). In every pinniped species studied to date, mothers appear to accept or reject pups using olfactory cues (Insley et al. 2003). For instance, female Australian sea lions (*Neophoca cinerea*) are capable of discriminating their own pups from

others using olfaction in the absence of other cues (Pitcher et al. 2011). In an experiment performed by Kaufman et al. (1975), the skin of a dead weddell seal pup was attached to a live pup. The live pup was then accepted by the mother of the dead pup from which the skin had been taken. These observations suggest that olfactory cues play a crucial role in individual recognition and reunion of mothers and pups (Insley et al. 2003).

## Conclusion

Communication plays an important role in the lives of pinnipeds, from mating, to establishing and maintaining territories, to mother-pup reunification (Winn and Schneider 1977; Van Opzeeland et al. 2008). Pinnipeds use a variety of modalities to communicate. The most well-known, and best studied, form of pinniped communication is acoustic communication (Miller 1991). Pinnipeds also use forms of visual, tactile, and chemical communication (Dudzinski et al. 2009; Winn and Schneider 1977). Visual signaling is an important aspect of pinniped communication, yet remains severely under-studied (Miller 1991). Chemical communication also plays an important role in the lives of all pinniped species, with olfaction aiding in the identification of estrous females and the reunification of mother-pup pairs, but little is known about the chemical senses of pinnipeds and further anatomical and experimental research is warranted (Miller 1991; Winn and Schneider 1977). Communication has been studied in a number of pinniped species. However, gaps exist in what is known about the different forms of communication in polar pinniped species (Van Opzeeland et al. 2008). This is due to the fact that studies in polar pinniped species are impeded since many of their behaviors take place in isolated pack-ice areas or in offshore waters (Van Opzeeland et al. 2008). All ice-breeding pinniped species produce underwater vocalizations (Van Opzeeland et al. 2008). Recent developments in recording technologies have allowed researchers to acquire long-term acoustic data in remote areas which may help to improve

our understanding of polar pinniped behavior (Van Opzeeland et al. 2008).

## Pinniped Life History

Kristy L. Biolsi

Center for the Study of Pinniped Ecology and Cognition (C-SPEC), St. Francis College, Brooklyn Heights, NY, USA

The term pinniped comes from the Latin *pinna* for “fin” or “feather,” and *pedis* for “footed.” The taxonomic grouping Pinnipedia is not its own order, but rather is classified within the order Carnivora and consists of three families of marine mammals: Phocidae which are the true seals (i.e., earless seals), Otariidae, the sea lions and fur seals (i.e., eared seals), and Odobenidae, the walrus. Otariids are most easily distinguished by their external ear or pinnae, their large fore-flippers, and the ability to rotate their pelvis on land and walk quadrupedally. Phocids are distinguished by a lack of pinnae, their short, fur covered fore-flippers which have pronounced claws, and their inability to rotate their pelvis to walk quadrupedally on land. Odobenids are easily recognized by their general lack of fur and their pronounced tusks present on both the male and female walrus. Like the Otariids, they can walk quadrupedally on land (see Fig. 1). Taken together there are 33 extant species of pinnipeds which can be found in almost all marine waters of the globe, though distribution patterns can be seen between groups. Only phocids are found in the Arctic and Antarctic with the exception of the walrus (found in northern circumpolar waters). Most fur seal populations are restricted to the southern hemisphere, yet most other otariids are found in both hemispheres. The Hawaiian (*Monachus schauinslandi*) and Mediterranean monk seals (*Monachus monachus*) are the only tropic species,

**Pinniped Life History, Fig. 1** Photographs of three-species representative of the three pinniped families: (a) Family Phocidae, *Phoca vitulina* (harbor seal); (b) Family Otariidae, *Zalophus californianus* (California sea lion); (c) Family Odobenidae, *Odobenus rosmarus* (walrus)

and the Baikal seal (*Pusa sibirica*) is the only freshwater species. While pinnipeds inhabit all climate zones, they are not currently in the waters off the coast of Asia or India, and it is suggested that these waters are nutrient poor and therefore do not have a stable food supply for them (Riedman 1990).

## Evolution

Pinnipeds are thought to have evolved from their terrestrial ancestors, a group termed the Canoidea. Since Canoidea consists of multiple groups such as the ursids (bears), mustelids (weasels and otters), and canids (dogs), there has historically been argument within the scientific community as to the specific phylogenetic origins of the three pinniped families (Arnason et al. 2006; Lowenstein 1986; for a recent in-depth review of the debate see Koretsky et al. 2016). There are two views of their ancestry centered around the question of whether pinnipeds evolved from the same, or two different, phylogenetic lines. The diphyletic view states that both otariids and odobenids evolved from a bear-like ancestor around 25 million years ago (MYA) in the early Miocene while the phocids evolved from a mustelid or otter-like ancestor about 20 MYA, mid-Miocene (Koretsky and Holec 2002; Koretsky and Sanders 2002; Koretsky and Barnes 2003; Repenning 1976; Riedman 1990). While this view has been supported by the fossil record, recent molecular

evidence (e.g., DNA and RNA from extant species) suggests a monophyletic view with phocids and otariids descending from a common bear-like ancestor approximately 25 MYA (early Miocene) (Arnason et al. 2006; Dasmahapatra et al. 2009; Higdon et al. 2007, 2008). Despite conflicting evidence between the fossil record and molecular data, the current scientific consensus is the monophyletic view emphasizing a common ancestor; however, there is still some debate as to whether their most recent common terrestrial ancestors are ursids (bears) or mustelids (weasels/otters) (Berta and Churchill 2012; Boness and Bowen 1996).

Currently, of the 33-extant species of pinnipeds, four phocids and one otariid are listed as endangered with five phocid and two otariids listed as threatened (United States Fish and Wildlife (USFW) 2017). The Caribbean (or West Indian) monk seal (*neomonachus tropicalis*) was listed as threatened on March 11, 1967, and officially declared extinct as of October 28, 2008, being removed from the Federal Register after there had been no reported sightings of the seal in 50 years (USFW 2016). The Hawaiian monk seal (*Monachus schauinslandi*) was listed as endangered as of June 2, 1970 (USFW 2017), and critically endangered in 2008 (Karamanlidis and Dendrinos 2015; Littnan et al. 2015) with the recent population estimates at 1,112 individuals (National Oceanic and Atmospheric Administration (NOAA) 2015). While many pinniped populations are thriving, the factors influencing the 12 species listed as threatened or endangered

is the focus of many research and conservation efforts. Data show that the species' populations most in danger are those that inhabit the subtropical/tropical and Arctic/Antarctic regions of the globe (i.e., the more northern and southern latitudes), with more temperate dwelling species having stable and even thriving populations (Ferguson and Higdon 2006). This suggests that the more extreme areas of the globe may be more susceptible to both natural and man-made changes in the ecosystem. The underlying causes of this relationship between latitude and population stability is an area of research with investigations focused on the interactions between ecology and the life history of these varied pinniped species with an emphasis on climate change and prey distribution/availability (Ferguson and Higdon 2006).

The life history of pinnipeds is especially multidimensional because they are amphibious marine mammals that carry out critical life functions both on land and in the water. Their evolutionary ties to their terrestrial ancestors are demonstrated by their dependence on the sea for foraging while often breeding and giving birth on land. While the challenges of individual species vary, there are several generalizations that can be made within the life history of pinnipeds as a group with major differences being drawn between the phylogenetic lines of the phocids and otarioids (both the otariids and odobenids).

## Life Span

The life span of pinniped species ranges from 15 to 30 years with males having a shorter span due to the added biological stressors and potential injuries incurred during male-male aggressive encounters (see Table 1). It has been shown that many northern elephant seals (*Mirounga angustirostris*) die before reaching sexually maturity (age five) and significantly more die before reaching age nine at which time they are considered able to successfully compete for females and reproduce (Le Boeuf 1981; Reiter et al. 1981).

As mentioned above, it should be noted that chronological age of reproductive maturity (age at

which they are physically capable of breeding) is different than the age at which an animal successfully breeds. Typically, females breed once they hit sexual maturity (e.g., age two), but they may not give birth for a few more years (e.g., 4–5 years of age) (Boness et al. 2002; Riedman 1990). This discrepancy in age is more pronounced in male pinnipeds, perhaps because they must be physically capable of breeding, as well as physically large enough and behaviorally mature enough, to compete for territory/females. For example, walrus (*Odobenus rosmarus*) reach sexual maturity at 9–10 years of age but may not breed successfully until 13–16 years old (Fay 1982).

## Reproduction

Overall, both male and female pinnipeds must have sufficient mass and a healthy body condition, as well as the behavioral maturity, to breed successfully and reproduce. Sexually mature pinnipeds typically come ashore to their natal beaches (the site at which they were born) each year to give birth and then mate (Hoffman and Forcada 2012). Most otariids breed and give birth on land (Boness 1991; Franco-Trecu et al. 2015; Giardino et al. 2016), while 15 of the 18 phocid species mate aquatically (for an extensive review of aquatic breeding phocids see Van Parijs 2003). Most exceptions seem to be the ice seals, though data exist for a limited number of species. For example, evidence suggests that weddell seals (*Leptonychotes weddellii*) do not return to breed at the site where they were born (Davis et al. 2008), and they are the only large phocid to breed exclusively on fast-ice (i.e., ice attached to land). This may be due to female movement being restricted to consistent breathing holes in the ice (Cline et al. 1971; Bartsch et al. 1992; Harcourt et al. 1998, 2000).

As amphibious marine mammals, access to land for mating and/or birthing is critical and therefore timing of the annual breeding/pupping season is important. Female estrous cycles (when females are physiologically receptive for breeding) are annually synchronous for all pinnipeds, and mating occurs relatively quickly after the

**Pinniped Life History, Table 1** Information on 26 of the 33 extant species of pinnipeds. The data provide descriptions of general aspects of life history, organized by taxonomic family, including average mass of males and females of a species, existence of sexual dimorphism, life span, breeding strategy, lactation length, and percent milkfat. These data allow one to compare not only across species but across and within the phocid, otariid, and odobenid families. There is not sufficient data reported to provide a valid average of milkfat when “nd” is indicated in the table

birthing or parturition process. Though this timeframe between birthing and mating ranges somewhat among species, pinnipeds manage to synchronize in part through embryonic diapause or delayed implantation (Pomeroy 2011). In this way, the egg is fertilized and develops for approximately 7–10 days at which point development pauses at the blastocyst stage. Up to several months later (timing depending on the species), the embryo begins to develop again and implants into the uterus. This delay allows for the gestation period (including the diapause) to last approximately 10–12 months, ensuring that sexually mature males and receptive females arrive at their breeding sites at the same time each year.

Females give birth to one offspring per year of sexual maturity, though this is in part dependent on environmental factors such as food supply. Females may not give birth in a certain year if there are not enough resources available and her body is not in a healthy condition to sustain a pregnancy and lactation period (Boyd 2000; Shero et al. 2015). Twinning is rare, though has been documented (Hoffman and Forcada 2009; Riedman 1990), but research suggests that having twins may be detrimental as it decreases overall survival rates (Schultz et al. 2011). Alloparenting, a system in which individuals in the population other than the mother contribute to the care of the offspring, is rare but has been observed in the pinnipeds (Boness and Bowen 1996; Porter and Trites 2004; Schulz and Bowen 2005). It is most likely to occur when a female has lost her pup and fosters one that has lost its mother. Rarely, females will nurse a stray pup alongside its own. Males do not offer paternal care and, as stated, females do not usually care for offspring that are not their own. In fact, females have been known to behave aggressively toward nonfilial pups attempting to nurse. Infanticide has been observed but is usually caused by a nonfilial pup continuing to approach and attempt to nurse from an aggressive female, or by incidental injury due to proximity of an aggressive male-male interaction, though males have been known to kill pups through directed aggressive contact (Kiyota and Okamura 2005).

## Breeding Strategies

The details of mating strategies vary between species but most are polygynous and fall under either of two categories: harem or lek breeding systems (for a more detailed review see also Boness et al. 2002). In a harem system, the males fight for dominance rankings and access to receptive females on the beach. The most dominant male will spend the breeding season alternating between mating with many females and fighting off male challengers. Due to the physical nature of the male-male competition, many do not mate successfully until they are approximately 10 years old, even though sexual maturity may have been reached at 4 years of age (see “[Life Span](#)”). Males must acquire the size and the experience to win fights with the older, more dominant, males each year to gain access to females. For example, male northern elephant seals herd females inside their territory and keep other males out while male California sea lions (*Zalophus californianus*) compete to control specific locations on the beach. Unlike elephant seals, the female sea lions are free to move between these areas and therefore from male to male. Conversely, male harbor seals (*Phoca vitulina*) demonstrate a lek system and do not tend to have physical altercations with each other during the breeding season, but rather vocalize underwater to claim a territory therefore advertising their presence to females and deterring other males from that area (Van Parijs 2003). This difference in breeding style may be related to resource availability (food and breathing holes for ice seals), mating location (females of species that mate aquatically have more control over their mate choice), and the extent of sexual dimorphism (difference in physical size between males and females) found between various species (Van Paris 2003; González-Suárez and Cassini 2014; Modig 1996). Elephant seals have the largest degree of sexual dimorphism with the female northern elephant seals being an average of 1,300 pounds (600 kg) and males three to five times that at an average of 4,400 pounds (2,000 kg) (see Table 1). Their breeding strategy consisting of males fighting, often violently, to attain dominance and control of females favors

the evolution of a large body size. Harbor seals, on the other hand, demonstrate little to no sexual dimorphism, with males and females both averaging 245 pounds (110 kg), and they demonstrate little to no male-male aggression during the breeding season.

Reproductive success rates are based on number of offspring produced throughout the life span. While this is well defined and relatively easy to quantify for females of a given species, the data is less discernable for males. Regardless of the breeding strategy employed by a species, females give birth to one offspring per year (as noted, twins are rare and most do not survive to maturity), but males mate with multiple females each season making DNA testing the most reliable way to determine paternity and male success rate in a population. Due to the inherent difficulty of DNA testing for male success rates each year, most estimates are based on observed successful copulations and known dominance ranking of individual males. While this seems a reasonable assessment of male success, some data indicate that the most dominant males may not necessarily be providing the DNA for all offspring. For example, in northern elephant seals, “sneaker” males (young juveniles that “sneak” a copulation with a female) have been found to have contributed DNA to the population despite their lower dominance ranking and smaller size (de Bruyn et al. 2011). They have been successful in mating with females on the outer edges of a harem while the dominant male is engaged in a copulation, a fight with another male, or sleeping (hence the term sneaker male). This is interesting to note in relation to the evolution of behavioral/cognitive strategies in pinniped species.

### Maternal Dependency/Lactation

Care of offspring in pinnipeds centers around females and consists of protection from predators but primarily lactation or milk production. The mother-pup bond is strong during the lactation period and decreases significantly, and perhaps completely, after weaning. However, there is evidence that females behave in an affiliative manner with their kin when returning to their natal beaches to breed each year (Insley et al. 2003;

Schusterman et al. 2002), and there is some evidence that a California sea lion and its mother recognized each other for many years (Hanggi and Schusterman 1990).

Length of maternal dependence and lactation is generally divided between pinniped families, though it should be noted that other factors such as body size, ecology, foraging strategy, breeding/birthing location, and substrate all play an integrated role in the lactation strategy displayed by a given species (Bartholomew 1970). The phocids have the shortest lactation period ranging from four days (hooded seal, *Cystophora cristata*) to two and one half months (Baikal seal, *Pusa sibirica*; Pastukhov 1993), with a milk containing 40–50% fat (see Table 1). Otariids have a moderate nursing period between 4 months and 3 years with approximately 20–35% milkfat, while odobenids average a 2–3 year lactation period with about 30% milkfat, making them the pinniped with the longest period of maternal care (see Table 1). In fact, the walrus is the only species to have adopted a strategy of nursing their young in the water and having their young accompany them on foraging trips (Schulz and Bowen 2005). Therefore, three predominant lactation strategies (discussed below) can be seen among female pinnipeds which are generally divided among phylogenetic lines (and will be discussed as such for purposes of generalizing here), though the interactions between species ancestry, maternal mass, breeding substrate, thermoregulation challenges, milk composition, and various other ecological factors must not be overlooked (for a detailed review see Schulz and Bowen 2005).

A *fasting strategy* with little to no feeding is employed by phocids, though the harbor seal and ringed seal (*Phoca hispida*) have been documented to occasionally forage during this time. This may be correlated with their smaller body size, creating an inability to maintain enough energy reserves of their own throughout lactation (Boness and Bowen 1996; Bowden et al. 1992). This foraging during lactation may also be related to the availability of food close to shore, which may entice them to feed later in the lactation period (Boyd 1998). Length of lactation period is correlated with maternal mass and

percent of milk fat. The shorter the lactation period (for all pinnipeds), the more quickly fat reserves must be transferred to pups in the form of milk. Therefore, larger females can handle dumping more fat rich milk into their pups quickly. Of course, longer lactation periods mean more maternal care/time for pup growth and protection from predators; however, if fasting, there will always be an upper limit by which the female must return to sea or risk decreasing her reserves to the point by which she can no longer survive.

Ice-breeding phocids fast and have the shortest lactation periods of all pinnipeds, an advantage in an environment where a mother and pup are together on either fast (attached) or pack (floating) ice. For example, if the ice were to crack, break, and/or float away, a foraging female may not be able to find her pup upon returning to the ice. Breaking ice could crush or drown a pup. Also, in an extremely cold climate, adding blubber to a pup as quickly as possible will help it to thermoregulate appropriately.

Otariids have adopted a *foraging-cycle strategy* meaning that they alternate, or cycle, between nursing and foraging throughout the lactation period. This allows for a longer duration of maternal care, as the females replenish their energy reserves between nursing bouts. Whether this strategy is advantageous because it allows them to care for their pups for longer periods of time while not overly depleting their own reserves, or if it is more energetically demanding in the long run, is an area of continued study (Coltman et al. 1997; see Schulz and Bowen 2005). Perhaps the otariids, being small bodied as compared to most phocids, simply cannot acquire the energy reserves needed for fasting while lactating. These foraging bouts also add another challenge for these mother-pup pairs, as the pups are left alone in the rookery while the mother goes to sea to forage for 2–3 days. When the female returns after a foraging trip of 1–6 days, she and her pup must overcome the challenge of reuniting among hundreds of other mother-pup pairs (see Insley 2000; Trimble and Insley 2010).

A third strategy, the *aquatic nursing strategy*, is only found in the odobenids. The walrus, having the longest period of maternal care (2–3

years), has adopted a strategy of nursing in the water, as opposed to exclusively on land, and pups are known to accompany their mothers on foraging trips (Boness and Bowen 1996; Fay 1982). Walrus pups are born the least precocious of the pinnipeds, and this lengthy dependence on the mother allows for a longer maturation process of the pup prior to survival on its own.

## Foraging

The majority of a pinniped's fresh water supply is extracted from the food they eat and some is acquired through the metabolism of their blubber layer. Pinnipeds have been known to consume salt water in small amounts and metabolize it ending with a freshwater gain, but the process requires a lot of energy and is not an efficient source of hydration (Riedman 1990).

Pinnipeds tend to be generalists with diets consisting primarily of fish, crustaceans, and cephalopods and are typically solitary hunters though they have been documented hunting cooperatively when herding a large school of fish (Gales et al. 2004; Riedman 1990). A few species are specialists and as such have adaptations for feeding on certain prey items. For example, the crabeater seal (*Lobodon carcinophagus*) eats krill, and its teeth are formed in a way that allows them to gulp water and strain it out leaving the krill in their mouths on which to feed. Bearded seals (*Erignathus barbatus*) and walrus feed on mollusks and other bottom dwelling invertebrates. They both have substantial vibrissae, or whiskers, with which they use for rooting through muddy substrates and the walrus' mouth can produce suction strong enough to pull mollusks out of their shells. Ringed seals feed primarily on crustaceans and elephant seals prefer squid. The leopard seal (*Hydrurga leptonyx*), found in Antarctica, eats penguins and is the only pinniped known to prey on other seals (typically young crabeater seals) (Hocking et al. 2013).

Foraging occurs at varying depths and durations based on species, but a notable mention with significant diving abilities is the elephant seal, known to make foraging dives to an average

depth of 1,680 feet (512 m) and 22 min in length (Heerah et al. 2014). The elephant seals' maximum recorded dive depth is 6,562 feet (2,000 m) and for a duration of approximately two hours, rivalling that of the sperm whale, making it one of the deepest diving marine mammals. These long dives are in part possible due to their large size which increases the amount of oxygen they can store and therefore increasing time spent at depth and decreasing the need to come up for air frequently.

As amphibious mammals, pinnipeds must balance the energetic resources needed to leave a terrestrial haul-out location and actively search and hunt for food with the energy gained by the food they consume. Foraging patterns are correlated with, and generally divided by, ancestry with the phocids most likely to employ an *income strategy* and otarioids using a *capital strategy* (Arthur et al. 2016; Stephens et al. 2014). For example, the hooded seal (a phocid) tends to favor a capital strategy based on fewer trips with longer travel distances to and from foraging sites of large density prey (through which they increase reserves in body mass – creating capital reserves), while the California sea lion (an otariid) favors an income strategy with shorter, but more frequent, foraging trips (less reserve and more frequent income replenishment needed). The quality of prey is also important as traveling a long distance for many poor-quality fish will not be energetically advantageous over traveling a shorter distance for fewer fish, if the smaller fish population is a much higher quality. Latitude ranges will, in part, determine prey distribution with colder/temperate waters, and therefore middle latitudes, having higher productivity and prey item availability.

Therefore, factors correlated with a capital versus income foraging strategies (and with the phocid and otarioid groups, respectively) are the species' overall body size, maternal care/lactation strategy (see “[Reproduction](#)”), and global distribution. Whether the driving factors of strategy are ancestry, physical properties of the species (e.g., overall size and depth of blubber layer), water temperature and quality, or habitat ecology including prey availability/distribution is an active area of research. These factors are

inherently interconnected and it is probable that rather than a direct causal link, the best predictor of foraging strategy will be an interactive model of the aforementioned variables.

## Molting

Molting is another event tethering these amphibious marine mammals to land. All species molt, during which time they undergo a relatively drastic shedding of their fur accompanied by the growth of a new coat. The timing of the molt depends on the species as well as the age within species. For example, molting is staggered by age in the northern elephant seal with yearlings hauling out in the fall, adult females in the spring after foraging trips following the breeding season, and adult males molting in the summer (Longstreth 2016; Riedman 1990). Pups of all species go through an initial molt of their lanugo, which is a layer of fur that develops in utero and serves to help newborn pups maintain their core body temperature until their blubber reserves have increased. Some pups (e.g., the harbor seal) shed their lanugo in utero (prior to birth), but most pinnipeds shed it by the end of weaning (Brueimmer 1975; Riedman 1990).

While many terrestrial mammals are known to shed throughout the year with marked changes in this based on seasonality/temperature, the pinniped molt is notably different in large part due to their semiaquatic lifestyle. The growth of new fur requires increased blood flow to the surface of the skin. This is counter to the needs of marine mammals in that they often shunt blood away from the surface to their core (major organs and large muscles) to limit heat loss to the aquatic environment (Erdsack et al. 2012). Therefore, growing new fur and maintaining their core body temperature are essentially at odds. Many pinnipeds compensate for this by not shedding and growing hair continuously throughout the year, but rather by condensing this process into a yearly event or molt. During this time, they remain on land for relatively long periods of time allowing the blood to remain at the surface of the skin providing the nutrients needed for new hair growth.

Among the pinnipeds two main molting strategies emerge: one being to increase body mass (foraging), then fast and remain out of the water (more blood supply to the skin/new fur) allowing for a short molt duration, while the second is to continue to forage throughout the molt, entering the water (interrupted blood supply to the skin/new fur), thus requiring a longer molt duration. Which strategy is employed can be generalized as a division between the phocid and otarioid lines. Harbor seals (a phocid) have relatively short molts lasting on average 1 month while the molt of a California sea lion (an otariid) can last up to a few months with a peak in shedding lasting a month or more. However, it must be noted that there are many interacting variables underlying reliance on these strategies other than ancestry (see “[Foraging](#)”).

An extreme strategy in the phocid line is employed by elephant seal species and the Hawaiian monk seal. They haul out once per year and not only shed their fur but their skin as well. Large patches of their hair and skin peel off to reveal new skin and fur below. This process has been termed a *catastrophic molt* and requires a lot of energy and a large blood supply to the surface of the body (Ling 1970). Therefore, these seals fall under the category of a short duration molt during which time they fast and remain on the beach until its completion.

## Migrations

Pinnipeds have a consistent and annual migratory pattern primarily based on feeding, breeding/birthing, molting, and seasonal ice (for the Arctic/Antarctic species) (see Luschi 2013). They migrate to breed and give birth, traveling to warmer waters for the new pups that lack a thick blubber layer for thermoregulation and then to cooler waters with greater productivity and more prey items. An exception to this are many of the ice seals as they prefer to breed when the ice is most prevalent allowing for larger areas for breeding and pupping and a lowered chance of fast ice breaking off and becoming a moving ice floe. If

this were to happen during the weaning period, females could be separated from their pup (see “[Reproduction](#)”).

The methods by which pinnipeds navigate during these migrations are not completely understood. Researchers believe that it is a combination of their ability to use underwater landmarks, water and wind currents, water temperature, and even celestial bodies. Mauck et al. (2008) found that the harbor seal can utilize the stars in the night sky to navigate, and Ronald and Healey (1981) found that juvenile harp seals (*Pagophilus groenlandicus*) are successful on their annual northern migration (up to about 3,100 miles/5,000 km) on their first trip with no adult seal present. This indicates that, at least in some cases, aspects of these migrations may be innate.

## Conclusion

The life history of a species encompasses a pattern of resource acquisition and utilization in support of the interactions between lifespan, foraging, and reproduction strategies (which may or may not include migratory patterns in relation to prey and/or mate availability and access). This interrelated web of factors is based on the evolutionary history of a species, the past and present environmental pressures, and the ecological systems in place. The above sections are an overview of the basic points of life history within the pinnipeds but, as with any taxonomic group, the physiological and behavioral aspects of these animals are not only influenced by the past and current environments but will continue to be shaped by their environments to come.

## Pinniped Morphology and Locomotion

Randall Davis

Texas A&M University, 200 Seawolf Parkway,  
OCSB, Galveston, TX, USA

Locomotion enables animals to actively seek food, avoid predators, interact with conspecifics, and respond to diel and seasonal changes in the environment (e.g., seek shade, migrate). However, locomotion can be energetically expensive, so it must enhance survival and fitness. Although animals display a variety of locomotory modes, there is a convergent evolution toward minimizing the energetic cost of terrestrial, aerial, and aquatic locomotion. This is the dominate trend in the form and function of aquatic locomotion in marine mammals including pinnipeds.

Taxonomically, pinnipeds are a diverse clade of carnivorous, semiaquatic marine mammals whose fore and hind limbs are modified into flippers for efficient aquatic locomotion. There are 34 extant species divided into three Families: Phocidae (the earless seals or true seals), Otariidae (the eared seals: sea lions and fur seals), and Odobenidae (walrus). Fossils of the arctoid ancestors of pinnipeds can be traced to the Eocene (45 Mya), although fossil pinnipedimorphs only extend to the late Oligocene (27–25 Mya). Morphological and molecular evidence support a monophyletic origin for the three Families within the taxonomic Order of Carnivora (suborder of Caniformia, infraorder Arctoidea).

This chapter will focus on morphological and physiological adaptations that enable pinnipeds to maximize the acquisition of energy while minimizing the energetic cost. Nowhere is that better demonstrated than in the morphological adaptations for locomotion in water.

### Body Shape and Drag

Perhaps the most obvious adaptation in pinnipeds for an aquatic lifestyle is a streamlined body. The

convergent evolution of a fusiform (spindle-shaped) body shape has occurred in many aquatic vertebrates from fish to mammals, both extant and extinct (e.g., ichthyosaurs), in response to the greater density (820-fold) and viscosity (55-fold) of water compared to air. These two properties of water are responsible for *drag* (the resistive *force* to movement) experienced by a moving body, especially one that is bluff or rounded (i.e., non-hydrodynamic shape). In contrast, the more elongate, streamlined bodies of most marine mammals greatly decrease drag and the energetic cost of locomotion.

### Laminar and Turbulent Flow

Drag is influenced by flow around an object which can be laminar, transitional, or turbulent. When laminar, the fluid is ordered and flows in parallel layers around a body with no disruption like sheets of paper in a stack that slide past each other, with the nearest sheet stuck to the body (due to friction) and the farthest sheet unaffected by the body. However, in turbulent flow, the fluid layers are unsteady and form eddies like marbles that can slide and rotate relative to each other, again with the nearest marble stuck to the body and the farthest marble unaffected by the body.

Flow conditions around a body can be characterized using a *Reynolds number* (*Re*; the ratio of inertial forces to viscous forces used to characterize different flow regimes around an object). A *Re* less than  $2 \times 10^3$  is associated with laminar flow. As the *Re* increases, flow becomes unstable and susceptible to surface texture and disturbance that can cause turbulence. The transition to turbulent flow does not correspond to a single *Re* but may range from  $5 \times 10^5$  to  $10^6$  and depends on body shape and surface roughness. However, at very high *Re* ( $>10^6$ ), even minute disturbances will result in turbulent flow. The *Re* for all pinnipeds is high ( $\geq 10^6$ ) due to their large size, so flow is turbulent over most of the body at routine swim speeds.

### Drag

Drag can be explained by the viscous properties of water and the formation of a *boundary layer*. The viscosity of water results from the cohesive

interactions between water molecules called van der Waals forces and the adhesive molecular interactions of water to the boundary surface (e.g., skin). An ideal fluid without viscosity (inviscid) shows *slip* with respect to solid boundaries, so there is no frictional energy loss. However, when a real fluid moves past a body, it adheres to the surface and has zero velocity (i.e., no slip). Viscous forces create a velocity gradient until the fluid velocity approximates that of the free stream a short distance from the surface of the body.

There are two types of drag that can be explained by the formation of a boundary layer: *pressure drag* and *friction drag*. Pressure drag (also called form drag) is explained by Bernoulli's Principle: that is, for an ideal, inviscid fluid moving around an object, a decrease in velocity results in an increase in pressure and, conversely, an increase in velocity results in a decrease in pressure. For an ideal fluid, the pressures cancel each other and there is no net pressure or drag (d'Alembert's paradox). However, for a real fluid, the viscous forces cause the molecules adjacent to the object to slow. A boundary layer with laminar flow produces the lowest friction drag but is inherently less stable than turbulent flow. If the free stream velocity is fast enough, laminar flow around the rear half of a cylinder will separate causing vortices and a wake. As a result, the dynamic pressure in front of the object is not balanced by a counteractive pressure on the rear. A net force is exerted against the object, and this is what creates pressure drag. Most of the drag on a cylinder or bluff body (not streamlined) at high rates of flow is due to under-pressure that develops in the wake of the body. Pressure drag can be greatly reduced by using a streamlined or fusiform body shape. The optimum streamlined body has a fineness ratio (ratio of body length to maximum body diameter) of approximately 4.5 but can range of 3–7 with only a 10% increase in drag (Fish 1996, 1998).

Body shapes with a fineness ratio larger than 4.5 will have a greater surface-to-volume ratio and experience an increase in *friction drag* (also called viscous drag) which results from shear forces in the boundary layer due to the viscosity of water

and the adhesive molecular interactions of the water to the boundary surface (Vogel 1994). Taken together, pressure drag and friction drag contribute to the total drag on a body, and whether it is dominated by one or the other depends on body shape. The pressure drag on a streamlined body with a fineness ratio of ~4.5 and turbulent flow ( $Re > 10^6$ ), which is typical for pinnipeds, is small (~20% of total drag) relative to friction drag. Total drag is minimized by this ideal hydrodynamic shape which reduces the energetic cost of locomotion in marine mammals.

Total drag ( $D$ , Newtons) on a body can be calculated according to the equation:

$$D = 0.5 \times S \times \rho \times C_d \times U^2$$

where  $S$  is the wetted surface area of the animal ( $m^2$ ),  $\rho$  is the density of seawater ( $\sim 1024 \text{ kg m}^{-3}$ ),  $C_d$  is the nondimensional drag coefficient, and  $U$  is swimming speed ( $m \text{ s}^{-1}$ ). What is immediately apparent from this equation is the exponential increase in drag as a function of swim speed. Hence, the maximum speed will be constrained by drag, but also by mechanical efficiency and thrust production. The other important factor is  $C_d$  which depends on the shape and texture of the body and is less for a hydrodynamic shape than for a bluff body (i.e., more rounded). Pressure drag will be most influenced by  $C_d$ , whereas friction drag will be most influenced by  $S$ . For two animals that differ in size but have the same  $C_d$ , pressure drag will be the same but friction drag will be greater for the larger animal because it has a larger surface area.

This calculation for passive drag does not include the effect of changes in body shape and flipper movement when an animal is actively swimming and maneuvering. Pressure drag will increase because the oscillating, propulsive motions of the body alter body streamlining. Appendages cause induced drag due to the generation of lift and also modify the flow of water around an animal which causes interference drag. Hydromechanical models for actively swimming animals exceed equivalent rigid bodies by three- to seven-fold. Active drag of a free-swimming animal is generally assumed to be

approximately three-fold greater than passive drag (Weihs 1974; Fish et al. 1988).

Drag is further increased when a body moves at the surface (*wave drag*) because it acts like the displacement hull of a ship producing bow and stern waves that radiate energy away from the body. Ultimately, maximum swimming velocity (i.e., hull speed) at the surface is constrained when the wavelength of the bow wave is equal to body length thereby trapping the animal within the bow wave. For some pinnipeds (e.g., sea lions), higher speeds at the surface can be achieved by porpoising (leaping out of the water) which greatly reduces drag while the animal is airborne. As we shall see, the reduction in drag reduces the energetic cost of swimming and increases aerobic dive duration.

### Thrust and Swimming Modes

When an animal is swimming at a constant speed, drag must be countered by a force that is equal and opposite to it – that force is thrust. To generate thrust and overcome drag during aquatic locomotion, pinnipeds have evolved flippers with high (3–9) aspect ratios ( $\text{span}^2 \div \text{projected area}$ ) to improve thrust production and propulsive efficiency (Fish 2000). With their streamlined cross sections, flippers also function as control surfaces that provide maneuverability and stability. Since pinnipeds evolved from quadrupedal land mammals, morphological changes for aquatic locomotion can be traced in the fossil record and include foreshortening of limbs and enlargement of the hands and feet with webbing into high-aspect ratio propulsive surfaces (Fish 1996). These morphological changes in locomotory mode which resulted in pelvic oscillation (seals and walrus) and pectoral oscillation (sea lions and fur seals) also permitted movement on land. The evolution of these modes of swimming were associated with performance changes from drag-based propulsion (paddling) to lift-based that generate thrust throughout the stroke cycle and increase propulsive efficiency (thrust power-to-total mechanical power output  $\sim 0.75\text{--}0.90$ ), power, and speed (Feldkamp 1987a; Fish 1996, 2000).

Pinnipeds exhibit a variety of aquatic modes of locomotion, but they regularly haul out on land or ice to give birth, breed, and rest, often in large groups called rookeries. Seals and walrus swim using pelvic oscillation in which the posterior body is laterally undulated moving the paired hind flippers in the horizontal plane. As they are swept to one side, the leading flipper closes (adduction of the digits) while the trailing flipper maximally expands (abduction of the digits) to generate thrust. At the maximum lateral extent of the undulation, the posterior body sweeps in the opposite direction and the flippers switch their respective open and closed positions. As a result, thrust is generated continuously (by one flipper) through an entire stroke cycle as the flippers alternate opening and closing as the body undulates. The angle of attack of the open flipper is controlled by the ankle analogous to the peduncle in cetaceans.

Sea lions and fur seals use their fore flippers as both lift-based hydrofoils and drag-based paddles. The oscillating fore flippers act as hydrofoils generating thrust and lift as they move vertically through the water over the initial three-quarters of the stroke and as paddles during the final phase of the stroke which lasts about 1 s. Hence, thrust is produced throughout most of the stroke using lift, although the majority is generated during the paddle phase by drag. The hind flippers generate no thrust but contribute to maneuvering. For all pinnipeds, oscillation of high-aspect hind flippers (seals and walrus) and fore flippers (sea lions and fur seals) produces maximum mechanical efficiencies of 0.8 and 0.88, respectively.

Although pinnipeds often appear awkward on land, they are capable of remarkable agility, stamina, and speed. Otariidae can rotate their hind flippers forward, and their fore flippers bend at the wrist, which gives them substantial surface contact for good traction. As a result, they can move rapidly over slippery rocks or ice, much faster than humans in boots. They are also good rock climbers capable of scaling cliffs and fence enclosures. Although walrus can also rotate their hind flipper forward, their large body mass limits agility and speed. However, they have been known to trek inland for substantial distances.

Phocidae move more awkwardly (hitching action) because they cannot rotate their hind flippers forward. However, they also can move remarkably fast (an adult male elephant seal challenging another male on the beach can move as fast as a running human) over short distances or slowly over long distances (the mummified remains of crab eater and leopard seals have been found many kilometers from the sea in the Dry Valleys of Antarctica). Why they make these journeys remains a mystery. Ringed seals have large fore flippers, long claws, and phalanges that bend. This gives them a unique “hauling grip” which they use on the ice when moving forward and for maintaining breathing holes by abrading the ice.

## Energetics

### Power Produced by Contracting Muscles

Animal movement is generated by the contraction of muscles. Muscles act as biological engines that convert *chemical energy* (metabolism) into *power and mechanical work*. Muscles act only as *pulling* engines because they generate force by *actively shortening* and then lengthen by either the contraction of an opposing muscle or by the effect of an elastic structure. Muscles used for locomotion in vertebrates are classified as skeletal muscle (as opposed to cardiac and smooth muscle). The energy for contraction is provided by adenosine triphosphate (ATP), and the energetic cost of locomotion results primarily from the increased energy metabolism of contracting muscles used for propulsion.

The contracting muscles in marine mammals move flippers and flukes to generate thrust to overcome the load created primarily by drag but also viscoelastic forces in the muscles. The power generated by the contracting muscles is translated into the power associated with locomotion (thrust  $\times$  velocity). While drag increases with  $U^2$ , locomotory power increases with  $U^3$  which makes high-speed swimming energetically costly. As a result, routine swim speeds of most pinnipeds remain low at 1–3 m s<sup>-1</sup>, although higher speeds occur during burst swimming when energy economy is not important (e.g., pursuing prey,

avoiding predators). Furthermore, aerobic metabolic efficiency in the muscle is only ~15% and propulsive efficiency (thrust power  $\div$  total mechanical power output) is, at best, ~85% (range 75–90%) in marine mammals that use lift-based propulsion. Hence, the overall aerobic efficiency (the aerobic conversion of food energy into movement) is only ~13%. This means that the aerobic power for submerged swimming actually increases at  $\sim 8 \times U^3$ .

### Cost of Transport (COT)

The COT (J kg<sup>-1</sup> m<sup>-1</sup>) is the energetic cost (J) of moving 1 kg of body mass 1 m and is calculated by dividing locomotory metabolic rate by speed. The COT decreases with speed to a minimum value that has a mass-specific scaling factor that varies with the mode of locomotion (e.g., quadrupedal running mammals [8.46 g<sup>-0.40</sup>], endothermic surface swimming birds and mammals [23.87 kg<sup>-0.15</sup>], marine mammals [7.87 kg<sup>-0.29</sup>], salmon [2.15 kg<sup>-0.25</sup>]) and enables an animal to cover the largest distance for the smallest energy cost (Taylor et al. 1970; Schmidt-Nielsen 1997; Williams et al. 1992). The decrease in minimum COT with increasing body mass results from lower mass-specific metabolic rates during exercise (similar to resting metabolism) and higher optimum speeds for large animals. The mean minimum submerged COT for harbor seals, California sea lions, and southern sea lions is 2.6 J kg<sup>-1</sup> m<sup>-1</sup> for an average mass of 57 kg. For the harbor seals and the California sea lions, minimum COT increases a modest 16% as speed increases to 3.4 m s<sup>-1</sup>.

### Swim Speed

Measuring the swim speed of marine mammals at sea is very difficult. Gauging the speed of an animal swimming at the surface from a boat is inaccurate and impossible for submerged swimming. Transit speeds at the surface determined with Argos satellite locations or GPS do not reflect the animal's three-dimensional movements, so they are a minimum estimates. Vertical descent and ascent speeds alone underestimate actual swim speed, and calculating speed using the rate of depth change and descent or ascent

angle is not accurate for pitch angles less than  $45^\circ$ . The most accurate method is to attach small, animal-borne instruments with calibrated speed sensors, but this approach is expensive and logistically challenging. Even with these instruments, animals need to be monitored over long-time periods to generate an accurate mean value, and this has only been done for a few pinnipeds. However, even a mean value may disguise important and interesting differences in speed associated with changes in behavior, which in itself may be difficult to determine. As a result, the literature is full of values for swim speed that may or may not be accurate or representative of average or routine values and are difficult to place in a behavioral context. Burst speeds are even more suspect because they are often of short duration and generally estimated from a boat or in captivity. Nevertheless, so-called routine and burst speeds are worth considering with the understanding that most are, at best, an estimate. The most striking aspect when comparing the routine swimming speeds of marine mammals ranging in size from the smallest (sea otter) to the largest (blue whale) is the very narrow range. Despite differences in size, feeding ecology and diving behavior, the routine swim speeds of most marine mammals fall in the range of  $1\text{--}3\text{ m s}^{-1}$ .

## Buoyancy

The density of fresh water ( $1\text{ g cm}^{-3}$ ) is 820-fold greater (839 for sea water) than for air ( $1.33 \times 10^{-3}\text{ g cm}^{-3}$ ) but only 1.1-fold greater than for blubber ( $\sim 0.9\text{ g cm}^{-3}$ ). In contrast, lean tissue (e.g., muscle) has a density ( $1.06\text{ g cm}^{-3}$ ) that is slightly greater than for sea water. Hence for marine mammals, net buoyancy (Newtons, N) will be the sum of the positive buoyancy from air in the lungs or trapped in the fur (sea otters and fur seals only) and from blubber and the negative buoyancy from lean tissue. However, air is compressed as the animal descends during a dive resulting in a loss of buoyancy as a function of depth. In contrast, blubber is incompressible so its contribution to buoyancy is independent of depth but may change seasonally. Hence, an animal's

buoyancy will be dynamic and depend on seasonal body composition and the ambient pressure during dives.

During descent, compression of the lungs can result in the transition from positive buoyancy at the surface to negative buoyancy. As a result, pinnipeds can go from active stroking to stroke-and-glide until a depth at which point they are negatively buoyant, stop stroking and glide to the bottom of the dive ( $\sim 300\text{ m}$ ). Gliding is an energy-conserving locomotory strategy that can potentially reduce diving metabolic rate in elephant seals and was later confirmed for other species of marine mammals including bottlenose dolphins, blue whales, and Weddell seals. The effect of negative buoyancy on metabolism was measured for Weddell seals diving from an isolated ice hole. Dives with prolonged gliding during descent had a 27.8% (range 9.2–59.6%) reduction in energetic cost compared with those using stroke and glide or continuous swimming over the same total distance (descent and ascent).

Not all individuals within a population will have the same body composition. On average, the thinner seals glide during descent whereas the fatter seals use stroke-and-glide locomotion. Hence, pinnipeds adopt different stroke patterns according to their individual buoyancies.

Drift dives are an interesting manifestation of changes in buoyancy. They were first described for an adult northern elephant based on time-depth profiles and swim speed during the postbreeding foraging trip and occur in bouts (ca. 2–10 drift dives per day). During drift dives, seals stroke to a depth where they become negatively buoyant (due to lung collapse) and then sink passively in a supine (belly-up) orientation to a depth of 300–400 m for about 23 min, although this varies with body composition. Drift dives have also been observed in southern elephant seals and Weddell seals. However, their function remains uncertain. There has been speculation that they are associated with digestion following bouts of foraging dives. This seems reasonable, but there is no evidence that a suspension of active foraging is necessary for digestion or that it can be postponed until a bout of drift dives. In Weddell seals, digestion and assimilation occur during long foraging

bouts. A more likely explanation is that drift dives are associated with sleep.

## Summary

1. The convergent evolution of a fusiform body shape in aquatic vertebrates decreases drag resulting from the greater density (820-fold) and viscosity (55-fold) of water compared to air.
2. Drag is influenced by flow around an object which can be laminar or turbulent and characterized by a *Reynolds Number* ( $Re$ ). Due their large size ( $>1$  m length), the  $Re$  for all pinnipeds is high ( $\geq 10^6$ ), so flow is turbulent over most of the body at routine swim speeds.
3. There are two types of drag that can be explained by the formation of a boundary layer: *pressure drag* and *friction drag*.
4. Pressure drag is greatly reduced by a streamlined or fusiform body shape with an optimum fineness ratio 4.5 (range of 3–7) which delays boundary layer separation and formation of a wake.
5. Body shapes with a fineness ratio larger than 4.5 will have a greater surface-to-volume ratio and experience an increase in friction drag (also called viscous drag). Taken together, pressure drag and friction drag contribute to the total drag on a body, and whether it is dominated by one or the other depends on body shape.
6. The pressure drag on a streamlined body with a fineness ratio of ca. 4.5 and turbulent flow ( $Re \geq 10^6$ ), which is typical for pinnipeds, is small (~20% of total drag) relative to friction drag.
7. The drag coefficient ( $C_d$ ) depends on the shape of the body and is less for a hydrodynamic shape than for a bluff body. Pressure drag will be most influenced by  $C_d$  whereas friction drag will be most influenced by surface area ( $S$ ). For two animals that differ in size but have the same  $C_d$ , pressure drag will be the same but friction drag will be greater for the larger animal because it has a larger surface area.
8. Active drag of a free-swimming animal is generally assumed to be approximately three-fold greater than passive drag.
9. Swimming submerged at a depth of three body diameters prevents wave drag which can augment total drag 4 to 5-fold.
10. Flippers and flukes with high (3–9) aspect ratios to improve thrust production and propulsive efficiency also function as control surfaces that provide maneuverability and stability.
11. The most derived and efficient modes of aquatic locomotion include pelvic oscillation (seals and walrus) and pectoral oscillation (sea lions and fur seals) with performance changes from drag-based propulsion (paddling) to lift-based that generates thrust throughout the stroke and increases propulsive efficiency (thrust power-to-total mechanical power output ~0.75–0.90), power and speed.
12. Although pinnipeds often appear awkward on land, they are capable of remarkable agility, stamina, and speed.
13. Animal movement is generated by the contraction of muscles which convert *chemical energy* (metabolism) into *power and mechanical work*. The contracting muscles in marine mammals move flippers and flukes to generate thrust to overcome the load created primarily by drag but also viscoelastic forces in the muscles.
14. The power generated by the contracting muscles is translated into the power associated with locomotion (thrust  $\times$  velocity). Since drag increases with  $U^2$ , locomotory power increases with  $U^3$  which makes high-speed swimming energetically costly. As a result, routine swim speeds of most marine mammals are 1–3 m s<sup>-1</sup>. The overall aerobic efficiency (the aerobic conversion of food energy into movement) is only ~13% which means that the aerobic power for submerged swimming actually increases at  $\sim 8 \times U^3$ .
15. There is a convergent evolution toward a minimum COT for running terrestrial mammals and subsurface swimming marine

mammals *of similar size* that optimizes the cost of locomotion.

16. The mean minimum submerged COT for harbor seals, California sea lions, and southern sea lions is  $2.6 \text{ J kg}^{-1} \text{ m}^{-1}$  for an average mass of 57 kg.
17. Despite differences in size, feeding ecology and diving behavior, the routine swim speeds of most marine mammals fall in the range of  $1\text{--}3 \text{ m s}^{-1}$ .
18. Seals adjust their swimming mode (continuous stroking, stroke-and-glide, gliding) during descent and ascent in response to changes in buoyancy.
19. Drift dives are probably associated with sleep at depth. Seals may be negatively or positively buoyant at depth, and this will determine whether they drift downwards or upwards.

## Definition

The pituitary gland is a pea-shaped endocrine gland hanging from the neural extension of the base of the hypothalamus. It is responsible for regulating and maintaining the normal physiological functions of the body.

## Introduction

The pituitary gland is ubiquitous throughout the vertebrates. It is sometimes referred to as the master gland of the body because it controls the secretion of other glands via its hormones. Hence, most of the pituitary hormones are tropic hormones in nature, that is, they stimulate the other endocrine glands to release their hormones. The pituitary is functionally and anatomically divided into three lobes which secrete their signaling molecules into the bloodstream. The anterior lobe

(Table 1) produces growth hormone (GH), adrenocorticotrophic hormone (ACTH), thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), and prolactin (PRL). These hormones are synthesized and stored as vesicles inside the glandular cells of the anterior pituitary and are released via exocytosis when acted upon by the hypothalamic hormones.

The posterior part of the pituitary stores oxytocin and vasopressin. Unlike the anterior pituitary hormones, these are not synthesized in the pituitary but are manufactured by the neurosecretory cells, a special class of neurons that release hormones. These neurons are located in the hypothalamus, the axons of which terminate in the posterior pituitary region. These hormones are shipped down the axon, a long narrow extension of neuronal cells, and are stored as vesicles in the axonal endings (Barrett et al. 2009). The intermediate lobe forms a thin layer of cells that produce melanocyte-stimulating hormone (MSH), which has its role in skin pigmentation. Except PRL and GH, all the anterior pituitary hormones are tropic in nature. The posterior pituitary hormones

along with PRL and GH are nontropic and directly affect the site of action (Barrett et al. 2009).

## Morphology

The pituitary gland sits just behind the nose bridge and is located in the mid-line from a mid-sagittal view, inferior to the optic chiasm (Fig. 1). It rests inside a bowl-shaped depression of the sphenoid bone called the *sella turcica* (named after its resemblance to Turkish horse saddle). The roof of the depression is surrounded by a dura mater (a membranous layer that surrounds the brain and the spinal cord) known as the *diaphragm sella* which covers the hypophyseal fossa (the inferior part of the sella turcica). A hole in this diaphragm allows the vertical entry of pituitary stalk to join the hypothalamus. Hence, another term for the pituitary is the hypophysis (hypo = below; physis = outgrowth) as it appears as a protuberance of the brain hanging from the hypothalamus. The pituitary is richly supplied by the major arteries and dural venous sinuses to transport the released hormones on to its recipient sites.

**Pituitary Gland, Fig. 1** Mid-sagittal view of human head depicting the position of the pituitary gland

## Anatomy and Development

The pituitary is divided into two primary regions. This division of the pituitary is evolutionarily conserved and occurs in almost all vertebrates. The anterior part is called the adenohypophysis or the anterior pituitary lobe. It has abundance of glandular epithelial cells which are responsible for secreting the hormones. The upper portion of this lobe is called *pars tuberalis* while the lower region is called *pars distalis*, which is the site of endocrine secretion (Nussey and Whitehead 2013).

The second major region, called the posterior lobe, is mainly comprised of neural tissues, known as neurohypophysis or *pars nervosa*. The neural tissue is made up of axonal endings carrying the hormonal vesicles. These axonal endings arise from the supraoptic and paraventricular nuclei of the hypothalamus connected by a bundle of axons called the hypothalamo-hypophyseal tract. An extension of the hypothalamus forming a funnel-shaped cavity called pituitary stalk or the infundibulum connects to the posterior pituitary and accommodates the axon bundles and blood capillaries (Barrett et al. 2009). A bulge of the infundibulum forms the interface between the hypothalamus and the pituitary gland called the median

eminence. This is a specialized region where the portal vessels arise and axons from parvocellular neurosecretory cells (small neurons) from various nuclei terminate (Barrett et al. 2009).

In humans, the emergence of the pituitary is seen during the 4th week of gestation period. The embryological genesis of the lobes occurs separately. The anterior lobe is developed from the infolding of oral ectoderm, called *Rathke's pouch* (Fig. 2). The posterior lobe originates from the infolding of the neural ectoderm, specifically the base of the third ventricle (Fig. 2). This explains the differential composition of the cells in posterior and anterior lobes.

A third lobe known as the intermediate lobe is also present; unlike the other two lobes, it is not ubiquitous and it may be completely absent in some vertebrates such as the avians. It lies between the anterior and posterior lobe but is more closely associated with the anterior lobe due its shared embryological origin. This region is not very well defined in mammals such as humans, but it has been attributed to the secretion of melanocyte-stimulating hormone (MSH). Its function is more pronounced in the lower vertebrates such as rodents where this lobe's structure is well developed (Melmed 2010).

**Pituitary Gland,****Fig. 2** Embryological development of the pituitary gland**Vasculature**

A complex network of blood capillaries infiltrates the pituitary and its surrounding structures. The internal carotid artery branches off into several small arterioles that form the portal system of the pituitary. In contrast to the blood vessels that forms the blood–brain barrier, these capillaries are fenestrated (i.e., the tight endothelial junctions harbor multiple pores). This increases the permeability and allows free exchange of large molecules from the surroundings into the circulation (Melmed 2010; Nussey and Whitehead 2013).

The pars nervosa receives its blood supply from the inferior hypophyseal artery and the infundibular artery. The capillary network surrounding the region receives the neurosecretory hormones which are then drained into the inferior hypophyseal vein and eventually into cavernous sinus (Barrett et al. 2009). The microcirculation inside the anterior pituitary consists of a capillary bed which is linked to a network of capillary near the hypothalamus. This is known as the hypothalamo-hypophyseal portal system (Fig. 3). The superior hypophyseal artery joins a

complex grid of capillary bed known as the primary plexus traversing the median eminence and pars tuberalis. The same blood flows through the pars distalis via another capillary bed known as the secondary plexus which then drains into the cavernous sinus into the systemic circulation. Since the capillary blood drains into another capillary bed without passing through the heart first, this system is known as a portal venous system (Barrett et al. 2009). Hepatic portal system in the liver is another example of such system in the human body. The hypothalamo-hypophyseal portal is responsible for relaying the tropic factors from the hypothalamic nuclei into the anterior pituitary which in turn stimulates the glandular cells to release their respective hormones.

**Function and Site of Action of Different Pituitary Hormones****Anterior Pituitary Hormones**

1. **Thyroid-stimulating hormone (TSH):** It is released in response to hypothalamic thyrotropin-releasing hormone (TRH). TSH

**Pituitary Gland, Fig. 3** Hypothalamo-hypophyseal portal system

travels down the bloodstream and binds to the TSH receptors (a member of G-protein coupled receptors) present on the epithelium of the thyroid gland which increases the production and secretion of the thyroid hormones thyroxine (T4) and triiodothyronine (T3). Thyroid hormones upregulate the transcription of various genes increasing the protein synthesis (Brent 2012). This leads to a wide array of physiological changes such as increase in basal metabolic rate, increased heartbeat, increased number of mitochondria, increased oxygen utilization by the cells, etc. (Brent 2012).

2. **Growth hormone (GH):** It helps in growth and development of body and carries out various anabolic activities as well as aids in cell growth and proliferation, lipid breakdown, protein synthesis, etc. It mediates its effect by activating certain growth factors such as insulin-like growth factor 1 (IGF-1). GH is inhibited by somatostatin released by the hypothalamus as well as IGF-1 (Nussey and

Whitehead 2013). The release of GH is sexually dimorphic in nature, which is evident from the phenotypes of male and females in various species. It works in conjunction with the gonadal hormones such as the testosterone and estrogen to impart the sex-specific characteristics such as a higher cell proliferation and body growth in males.

3. **Adrenocorticotrophic hormone (ACTH):** It primarily functions by increasing the level of cortisol in the bloodstream by binding to its receptors on the *zona fasciculata* layer of adrenal gland cortex. Cortisol is a stress hormone that increases the blood glucose concentration, aids in metabolism of biomolecules, and suppresses the immune system (Nussey and Whitehead 2013).
4. **Prolactin (PRL):** It is physiologically relevant to females where it activates enzymes for lactose synthesis. It is a peptide hormone that acts on the mammary gland and stimulates milk production and its secretion into ducts (Nussey and Whitehead 2013). It also causes

maturation and growth of the mammary gland during pregnancy to prepare for the lactation. PRL has been noted to have suppressive effect on gonadotropin-releasing hormone (GnRH) release resulting in disruptions to normal ovarian cycle in females. This leads to a temporary infertile stage where the females stop menstruating, known as lactational amenorrhea (Nussey and Whitehead 2013).

5. **Luteinizing hormone (LH) and follicle-stimulating hormone (FSH):** These hormones are released by gonadotropes and act on testes (in males) and ovaries (in females). FSH in females induces growth and maturation of ovarian follicles (folliculogenesis) as well as stimulates the biosynthesis of estradiol (estrogen). In males, FSH aids in spermatogenesis by activating the Sertoli cells to synthesize androgen-binding protein (ABP) (Melmed 2010; Nussey and Whitehead 2013). Luteinizing hormone works in synergy with FSH and causes ovulation and formation of corpus luteum in females. In males, it acts on the Leydig cell for the production of testosterone.

### Posterior Pituitary Hormones

1. **Arginine vasopressin (AVP):** It is also called antidiuretic hormone (ADH) and its primary function is to restore the blood osmolarity to its normal physiological value. It increases the production of membrane channels that transport water molecules in the walls of the collecting duct of the kidney nephrons thereby increasing water reabsorption from urine (Melmed 2010). Vasopressin also increases the blood pressure by constricting the blood vessels. Changes to blood osmolality are detected by osmoreceptors in the hypothalamus which results in stimulation of neurosecretory cells in the hypothalamus to secrete AVP (Nussey and Whitehead 2013). The role of AVP has also been implicated in social behavior and bonding, especially male vertebrates (Heinrichs and Domes 2008). Arginine vasotocin (AVT) is a functional homolog to AVP as well as oxytocin and is found in almost all nonmammalian vertebrates including

teleosts, amphibians, and reptiles. It is likely that the vertebrate neurohypophyseal hormones have evolved from AVT (Knobloch and Grinevich 2014).

2. **Oxytocin:** Found in most of the mammalian species, this hormone mandates a diverse range of functions in mammals which include milk ejection reflex, uterine contraction during labor, sperm release, and behavioral responses such as maternal bonding (Jurek and Neumann 2018). It leads to rapid contraction of the uterine smooth muscle layer during parturition. The dilation of the cervix and the uterine during the onset of labor stimulates the hypothalamus to release oxytocin. The act of breastfeeding also activates this hormone where the tactile stimulation of the nipples causes the pituitary to release oxytocin, which in turn acts on the myoepithelial cells of the breast alveoli to release its milk into the ducts and eventually out of the nipples (Jurek and Neumann 2018). In other vertebrates, homologs of oxytocin play a similar role, for example, mesotocin, which is present in marsupials, reptiles, amphibians, and birds (Knobloch and Grinevich 2014).

### Regulation of the Pituitary Gland

**Hypothalamus:** It harbors several clusters of neurosecretory cells that synthesize and release various regulatory tropic and nontropic hormones (Table 2). The axonal endings of the parvocellular neurons terminate at the primary plexus, releasing their factors which travel down the secondary plexus and stimulate the anterior pituitary. In contrast, the magnocellular neurons (large neurons) terminate at the posterior lobe and release their hormones. Thus, hypothalamus directly controls the secretion of pituitary hormones (Nussey and Whitehead 2013). The hypothalamus is susceptible to environmental cues, and thus has a major implication on the tropic effect on the pituitary. Environmental stress can modulate the hormones released by the hypothalamic nuclei; for example, increase in the levels of cortical releasing factor (CRF) stimulates the ACTH and eventually

**Pituitary Gland, Table 2** Hormones synthesized by hypothalamus and their function

| Hypothalamic nuclei                   | Neuroendocrine cell  | Hormone(s) synthesized                                  | Function of the hormone                                      |
|---------------------------------------|----------------------|---------------------------------------------------------|--------------------------------------------------------------|
| Paraventricular nuclei                | Parvocellular neuron | Corticotropin-releasing hormone (CRH)                   | Stimulates the release of CRH                                |
| Preoptic area                         | Parvocellular neuron | Gonadotropin-releasing hormone (GnRH)                   | Stimulates the release of LH and FSH                         |
| Supraoptic and paraventricular nuclei | Magnocellular neuron | Oxytocin                                                | Uterine contraction during parturition; milk ejection reflex |
| Supraoptic and paraventricular nuclei | Magnocellular neuron | Vasopressin                                             | Vasoconstriction; fluid reabsorption                         |
| Arcuate nuclei                        | Parvocellular neuron | Prolactin-inhibiting hormone (PIH)                      | Inhibits the release of prolactin                            |
| Periventricular and arcuate nuclei    | Parvocellular neuron | Growth hormone-releasing hormone (GRH) and somatostatin | Stimulates the release and synthesis of GH                   |
| Paraventricular nuclei                | Parvocellular neuron | Thyrotropin-releasing hormone (TRH)                     | Stimulates the release and synthesis of TSH                  |

increases the blood cortisol levels. These stress cues ensue a differential response in other hormones such as the reduction in the gonadotropin levels and consequently changes to the female sexual cycle (Cameron 1997), increase in VP levels (Aguilera et al. 2008), increase GH levels (Delitala et al. 1987), etc.

## Negative Feedback Control

The hormones of the pituitary are well coordinated and regulated, and any imbalance may lead to severe clinical anomalies. Pituitary tumors are the most prominent cause of the abnormal secretion of the hypophyseal hormones. Depending on the hypo- or hypersecretion, a variety of conditions can develop, for example, *acromegaly* (excess GH), *Cushing's disease* (excess ACTH), hyperthyroidism (excess TSH), etc. Hypophysectomy (surgical removal of the pituitary) in animal studies has also shown several abnormalities, such as infertility, loss of sexual drive, underdeveloped sexual organs and reproductive tract, stunted growth, etc. Thus, the balance of hypophyseal hormones is crucial and is mediated by a complex neuroendocrine system that controls the activation and inhibition of the

endocrine glands. For example, in case of thyroid hormone homeostasis, a drop in T3 and T4 concentration in the blood is detected by the hypothalamus which results in release of TRH, stimulating the pituitary to secrete TSH. This leads to a rise in TSH levels in the blood plasma resulting in upregulation of thyroid hormone synthesis and release. An inhibitory response also works in synergy with the stimulation of TSH to keep the T3 and T4 plasma concentration up to a tolerable limit. This role is played by the thyroid hormone itself, which directly inhibits the release of TSH and indirectly inhibits TRH release from the hypothalamus. As the T3 and T4 levels in plasma elevate, the strength of this inhibitory response would also increase. This is an example of a negative feedback loop which functions almost similarly for other pituitary hormones.

## Place Versus Response Learning

Chad Ruprecht  
Microsoft Corporation, Redmond, WA, USA

### Definition

**Place learning** A form of spatial learning reflecting the acquisition and knowledge of an object/location's actual position in space, relative to a constellation of other visual cues.

**Response learning** A form of spatial learning reflecting the acquisition of a habitual response used to navigate to a location that does not reflect knowledge of a place based on surrounding cues.

### Introduction

Animals use a remarkable variety of methods to navigate their environments. Experimental psychologists have traditionally focused on how spatial relations between visual cues in the environment (landmarks, beacons, etc.) are acquired and whether these relations integrate together or compete for control over an animal's navigation. Early experiments trained animals to navigate a variety of mazes often aided by visual cues that bore a consistent spatial relationship to the goal (i.e., the end of the maze, often baited with food). By varying the position of visual cues surrounding the animal and/or maze, or by changing the animal's start location at critical points during training, three fundamental forms of spatial learning were observed: response learning, directional learning, and place learning. While each form of learning has the potential to support successful navigation, place learning is unique in that it suggests a much deeper understanding of where you are in space. Place learning, moreover, is a far more complex form of spatial learning; animals must process the current position of cues (as well as themselves) and make novel navigational decisions based on the arrangement of cues and/or their starting position in the maze. This behavioral distinction is echoed via investigations of the brain; neurobehavioral studies have found that successful completion of place navigation tasks depends more on the hippocampus region of the brain (a hotbed for learning and memory) compared to directional or response tendencies which tend to rely more on the caudate nucleus (responsible for motivated responding).

### What Fundamental Learning Processes Back Navigation?

For well over a century, researchers have attempted to describe *how* animals (including

our own species) learn. An animal might learn, for instance, that stimuli in the environment (S) are paired with a certain responses (S-R). In S-R learning (Thorndike 1898), a stimulus becomes paired with a response (the rat sees and reaches the choice point in a T maze (S) and turns left (R)). Over time, S-R links are “stamped in” as powerful habits, pending they eventually result in a reinforcing outcome. Another fundamental form of *how* animals learn involves understanding that one stimulus is associated with another stimulus (associative learning). Pavlov (1927) initially observed that if a biologically neutral stimulus (conditioned stimulus, CS, e.g., a metronome) was repeatedly paired with a biologically significant stimulus (unconditioned stimulus, US, e.g., meat), over time, his dogs would learn to associate the two stimuli, eventually salivating to the metronome (CS-US). Both S-R (habit) and CS-US (associative) processes support spatial learning but have varying significance when it comes to supporting response, directional, or place learning.

### Why Is Place Learning Different?

The first form of spatial learning, *response learning*, describes an animal learning to emit a programmed response or chain of responses (e.g., turn left, turn right, turn left) to reach a goal. The aforementioned habit building (S-R) mechanism is fundamental to response learning; either stimuli in the environment (S) or even the animals’ own proprioceptive feedback (i.e., orientation of the body relative to its orientation with respect to gravity) becomes strongly linked to a response (R). An example of response learning would be habitually learning a preset number of turns as you drive to your office building. At each turn point (S), you learn the next appropriate response (R) and chain these learned habits together. An important characteristic of response learning is that it is quite rigid and inflexible. If you’re habitual path to work is interrupted/rerouted by some unexpected construction, you may come to realize you don’t have a precise idea of where to turn next.

The second form of spatial learning, *directional learning*, describes an animal learning to head or approach a certain direction (e.g., east) in order to reach a goal. Directional learning is thought to work via a similar mechanism as Pavlov’s dogs; the animal is dropped into the maze and might learn to approach (sometimes referred to as sign tracking) the direction (north; CS) that ultimately leads them to the goal (US). This is in some ways more flexible than response learning in that the animal might make varying choices at different turn points but always head toward the direction of the goal.

The third form of spatial learning, *place learning*, describes an animal learning where something is in relation to other cues. Imagine observing that your office is west of a large clock tower and north of a flagpole. Assuming you can see the tower and flagpole, and have some knowledge of spatial relation (associations) between the three points, no matter the direction of your approach, you can successfully navigate to the *place* that your work is located. Place learning is inherently more flexible than either response or directional learning, meaning the animal heads to the correct location even if it’s coming from a different direction or viewing the cues from a novel orientation (see Fig. 1). That isn’t to say that place learning is cue independent; when the entire constellation of cues are shifted around, animals will still tend to head to the “place” in accordance with the current orientation of the cues.

### How Is Place Learning Captured?

The three forms of spatial learning were identified and isolated by observing rats navigating tabletop mazes in search of buried food or swimming to submerged platforms within a water maze (Fig. 2). In both cases, various extramaze (outside of the maze) cues are hung around the maze to serve as navigational landmarks the animal can utilize (or not). A typical spatial learning experiment tends to feature two phases: the training phase and the shift test phase.

**Place Versus Response Learning, Fig. 1** Tolman et al.'s (1946) famous sunburst maze is illustrated above. During training, the rat was dropped off at the lower start zone. Throughout training, the rat learned to take the same linear path to the goal. Extramaze cues (symbolized by the various icons) surrounded the maze throughout training and test. At test, a sunburst pattern with multiple pathways was introduced. If the animal evidenced response learning (an S-R habit), Tolman predicted it would take the middle route (now blocked) as it did during training. If the animal

evidenced a place tendency, Tolman predicted it would take an alternate route taking it efficiently to the correct "place" where the goal box should have been located, based on the constellation of extramaze cues. Tolmans' rats tended to evidence a place tendency, although some currently debate whether the rats used the rather salient lightbulb as more of a directional cue, simply approaching the signal (leading to a more associative CS-US interpretation)

Animals can be dropped off at a single start zone throughout training (Fig. 2a), dual start zones opposite from one another (Fig. 2b), or four corners of the maze (Fig. 2c) while the location of the buried food (goal) remains at the same location. Following training, the shift test involves experimenters shifting the maze by about 1/3 of its length on a single axis, so that the actual goal (within the maze) has moved, and an alternate "foil" location has taken the original goal's "place." Critically, no extramaze cues are moved; they still share the same spatial relationship with the "place" the goal had been during training. At test, the animal is dropped from one or more start zones. The critical shift trial examines whether the animal heads to the "foil" (more indicative of response/directional learning) or heads to the correct "place" (more indicative of place learning).

## What Parameters Affect Place Learning?

**Type of Navigation Task.** The Morris water maze (Fig. 2c) follows an identical training/shift test format, however, rats are typically dropped from four corners of the maze. These latter variants carry an advantage over path-based mazes such as the T maze (Fig. 2a) or plus maze (Fig. 2b) in that they don't force the animal to make a binary decision at the branch point (i.e., turn right or turn left at the middle of the plus maze). The Morris pool promotes more flexible utilization of visual cues to locate a hidden goal without clear choice points. It isn't surprising that the type of maze favors one form of spatial learning over the other; holding all other variables constant, a classic hedge maze or T maze tends to favor response learning, the plus maze tends to favor (at least initially) place learning followed by directional

**Place Versus Response Learning, Fig. 2** Three common mazes used to study spatial learning are illustrated as well as the “shift test” method used for assessing place learning. The top row (a) shows the T maze; the rat is dropped off at a single start zone and trained to approach the goal (a single arm baited with food). During the shift test, the entire apparatus is shifted 1/3 of its length on a single axis. If the animal turns left and visits the foil, it would evidence response/directional learning; if the animal turns right, and visits the ‘goal,’ it would evidence place learning. The middle row (b) shows the plus maze; the rat is typically dropped off at a two start zones and trained to

approach the goal (a single arm baited with food). During the shift test, if the animal turns and heads toward the foil, it would evidence directional learning; if the animal heads toward the ‘goal,’ it would evidence place learning. The bottom row (c) shows the Morris water maze; the rat is typically dropped off at four corner start zones and trained to swim to the goal (an elevated platform allowing to escape the aversive water). During the shift test, if the animal turns and swims toward the foil, it would evidence directional learning; if the animal heads toward the ‘goal,’ it would evidence place learning

P

learning (Skinner et al. 2003), and the Morris pool tends to favor place learning followed by directional learning as training trials increase (Hamilton et al. 2009).

**Amount of Training.** The amount of training on any maze, irrespective of type, has a rather large effect on the type of spatial learning evidenced during the shift test (Hamilton et al. 2009). Perhaps you’ve noticed that when first commuting to work, you paid close attention to

external cues to help better estimate your office’s location only to have this strategy give way (several commutes later) to highly habitual behavioral patterns (driving the same exact way each day). This same pattern generally holds true with rats in mazes: place learning tends to shift to response learning as training trials are increased. However, training effects vary depending on the type of maze, with place learning giving way to directional or response learning much sooner in

the plus maze (e.g., Packard and McGaugh 1996) than the more complex Morris maze (e.g., Hamilton et al. 2009).

**Salience of Intramaze Cues.** Intramaze cues (cues within the maze, including side walls, divots in the floor, etc.) are often kept to a minimum in such navigational studies to feature the effects of extramaze cues in supporting place learning. That being said, intramaze cues are impossible to completely devalue and play a strong role in determining which form of spatial learning is evidenced. Intramaze cues play an even more prominent role near the start zones and goal; start zones highly distinguishable via intramaze cues tend to support directional/response learning, essentially abolishing the early tendency for place early in training (Skinner et al. 2003). As Hamilton et al. (2009) emphasized, even slight scratches surrounding the walls of the Morris pool can abolish place learning preferences early in training (while it may cause a mess, Morris pools should be filled right near the surface to allow for a proper test of place learning!).

**Numerous Additional Factors.** In reality, spatial navigation is enormously complex and multiply determined. By no means an exhaustive list, spatial learning is affected by the organism's current or perceived orientation in space (e.g., Dudchenko et al. 1997), the shape or design of the spatial environment (e.g., Olton and Samuelson 1976), the availability of polarizing visual cues (Rodrigo et al. 1997), the current motivation of the animal (Tolman and Gleitman 1949), and the complexity of the task (Ruprecht et al. 2014).

**Brain (Limbic) Regions.** The distinction between spatial learning strategies is largely behavioral; however, growing evidence supports the notion that place learning and response learning depend on different structure/systems in the brain. Pharmacological agents blocking the hippocampus seem to abolish place learning behavior at the shift test (e.g., Packard and McGaugh 1996; Stringer et al. 2005). Pharmacological agents blocking the nucleus accumbens tend to disrupt S-R (response) processes (e.g., Packard and McGaugh 1996; Annett et al. 1989).

## Conclusions

For nearly all mobile animals, successful spatial navigation is key to the successful acquisition of rewards (food, shelter, mates) and the avoidance of negative outcomes (predators, famine, disease). Animals use a wide variety of interoceptive (signals within the organism's body) cues, such as kinesthetic (repeated muscular movements) and proprioceptive feedback, to support successful navigation while employing a remarkable array of external cues ranging from scents, magnetic fields, to triggers so remote and distant they continue to baffle scientists. Response, directional, and place learning can hardly explain the entirety of these evolved navigational capabilities. Rather, these distinctions try to carefully fit the more fundamental concepts of habit formation and association learning to the more complex phenomenon of spatial awareness and navigation. Our concept of *how* an animal learns about a place will continue to change and evolve. The extent to which a variety of search and navigation behaviors fall under the control of these central learning processes (habit, associative) is worth further investigation.

## Placoderm Life Histories

Kate Trinajstić and Brett Roelofs  
Molecular and Life Sciences, Curtin University,  
Perth, WA, Australia

## Synonyms

Armored fish

## Definition

Placoderm life history describes the reproduction and growth for species within the order Placodermi, which includes antiarchs, ptyctodonts, and arthrodires.

## Introduction

Life history strategies are difficult to determine from the fossil record. However, the global distribution and exceptional preservation from some fossil sites has resulted in much being understood about habitat, feeding strategies, reproduction, and growth within placoderms. Studies on the depositional settings in which placoderm fossils have been found, indicate that different species inhabited lacustrine, river, estuarine, and marine habitats. Reproductive strategies varied between the classes of placoderm from egg laying, resulting in a large number of offspring, to live birth with fewer offspring. There is little evidence of resorption and remodeling in the dermal bones that make up the placoderm armor and so lines of arrested growth provide a life record (skeletalochronology). Healed bite marks on the armor indicate that some species survived predations, and the occurrence of placoderms in the stomach of other species indicates the species for which placoderms were prey.

## Reproduction

The presence of intromittent organs in some male antiarchs, ptyctodonts (Fig. 1), and arthrodires indicate that these placoderms reproduced through internal fertilization (Ahlberg et al. 2009). In animals with internal fertilization, reproduction may occur through: oviparity in which fertilized eggs are deposited, ovoviviparity in which fertilized eggs are retained and then hatch within the female, and viviparity whereby the female gives birth to live young. The discovery of placoderm nursery sites (Downs et al. 2011; Olive et al. 2016; Gess and Trinajstić 2017) shows that all three reproductive methods were

**Placoderm Life Histories, Fig. 1** Reconstructed ptactodont reproductive organs and embryo position. (a) Generalised female ptactodont pelvic region. (Adapted from Miles 1967); (b) External morphology

of male ptactodont showing clasper organs. (Adapted from Miles 1967; Janvier 1996). (c) Position of the embryo and yolk sac within the mother. (Adapted from Long et al. 2008)

employed by placoderms. Species which birth live young tend to have longer reproductive cycles and fewer offspring that are born at a more advanced stage of development than species that lay eggs.

Within antiarchs, the reproductive structures include bony claspers in males, which aid in the delivery of sperm, and genital plates in females which protected the genital area from the hooks on the male clasper. These structures are only known for one genus, *Microbrachius*, and represents the earliest evidence of sexual dimorphism in jawed vertebrates (Long et al. 2015). The size of the male claspers differs between individuals, even though the body size of all the fish with claspers is approximately the same. This suggests that the claspers did not fully develop until sexual maturity and that sexual maturity occurred after morphological maturity. To date no embryos or larvae has been recovered associated with *Microbrachius*. However, large numbers of hatchlings are preserved for antiarch species such as *Bothriolepis* and *Asterolepis* and provide evidence that antiarchs were oviparous. In many of the hatchlings there is an opening in the ventral surface of the trunk shield, where a yolk sac could have attached (Downs et al. 2011).

All known examples of reproduction in Ptyctodonts indicate that they were viviparous (Long et al. 2008). Embryos are preserved in the abdominal regions in *Materpiscis*,

*Austroptyctodus*, and *Rhamphodopsis*. There are a number of bone fragments in the abdominal regions of *Ctenurella*, but these are not well enough preserved to be confidently identified as embryos. The maximum number of embryos from an individual ptyctodont (*Austroptyctodus*) is three with all embryos are identical in size, indicating that they were at the same developmental stage. A single embryo has been recovered from *Materpiscis* with an attached umbilical cord indicating that there was considerable maternal investment into the offspring. The ptyctodont embryos recovered were all positioned with the head in an anterior position (Fig. 1c), suggesting the young were born tail first. The young appear to be identical in morphology to the adults in terms of dermal plates and tooth plates. Identical tooth plates indicate that the young most likely fed of similar prey to the adults, only smaller.

Arthrodires, like sharks, utilized both oviparity and viviparity as a reproductive strategy. Some of the best-preserved evidence for reproductive structures comes from arthrodires from the Gogo Formation in the northern part of Western Australia (Long et al. 2009). Both male and female individuals have been recovered with several of the female coccosteomorph arthrodires (*Incisoscutum* and *Compagopiscis*) containing embryos within the abdominal cavity. In one specimen, two embryos of identical size are present; however, in a second individual one embryo is three times larger than a second

embryo. This indicates that the embryos were at different developmental stages and further suggests females had two uteri. One of the smallest embryos has intramittent elements preserved showing that these elements were present prior to sexual maturity (Johanson and Trinajstić 2014).

Intramittent elements are not known for *Eastmanosteus calliaspis*, a large pachyosteoromorph arthrodire from the Gogo Formation in Western Australia. This could be the result of preservation bias, as no specimens with the skeleton preserved posterior to the pelvis have yet been recovered. The smallest individual recovered to date is 25% of the adult size, which is comparable to the size of neonates in other arthrodires. This suggests that *Eastmanosteus* was viviparous. Intramittent structures have also not been recovered from one of the largest predatory placoderms, *Dunkleosteus*. A single egg case, that appears to contain dermal bone with a denticulate ornament, has been recovered and associated with this species (Carr and Jackson 2018).

Numerous very small phyllolepid (*Cowralepis mclachlani*) individuals, whose size is indicative of hatchlings, have been recovered from the same site as adults in Devonian aged rocks from Merriganowry, Australia (Carr et al. 2010). In one female specimen, an ovoid structure has been putatively identified as an egg sac. Other sites such as Red Hill (Daeschler et al. 2003) in North America and Strud in Belgium (Olive et al. 2016) also represent nursery sites, consistent with the phyllolepid arthrodires being egg layers.

The estuarine lagoonal environment of the Witpoort Formation in South Africa represents another location interpreted as the site of a placoderm nursery (Gess and Trinajstić 2017). An ontogenetic series of *Africanapsis*, a phlyctaenid arthrodire, includes individuals whose size is indicative of neonates and combined with the small number of individuals suggests they have been birthed, rather than hatched. No specimens with intramittent elements have been recovered from the site and this could indicate that females entered the estuarine nursery to birth their young, separated from the males of the species. Additional sites such as Red Hill in

USA and Strud Quarry in Belgium also support a viviparous nature for phlyctaenid arthrodires.

It appears that placoderms utilized nurseries in marine estuaries and shallow continental environments to lay eggs or give birth to their young. Within these nursery sites, male specimens are mostly absent suggesting that females separated from males to lay their eggs or give birth.

## Growth

Understanding evolutionary processes and determining the mechanisms that cause them are challenging without developmental and ontogenetic information, which unfortunately is rare in the fossil record. The dermal armor of the head and thoracic region in placoderms has resulted in excellent preservation of ontogenetic changes for placoderms. However, it means that placoderms are effectively growing in an armored box, meaning if one plate proportionally changes then the corresponding plate also needs to change. Placoderms evolved a huge variety of body morphs, which enabled them to occupy many different niche spaces.

The most important cause of variation in placoderms is ontogenetic growth. Juveniles are identified by plates of thin dermal bone, which do not overlap, deeply incised sensory lines and relatively large eyes. Studies done on the antiarch *Bothriolepis* demonstrate allometric growth with the greatest variation seen in those plates which show change through evolution (Werdlein and Long 1986). Heterochrony (changes in the rate and timing of development) plays a pivotal role in evolution and has been linked to changes in orbit size of both antiarch and arthrodires. Large orbits in adults, such as seen in the camuripiscids from Gogo are considered paedomorphic. Both antiarchs and coccosteomorphs show lengthwise growth before an increase in width. In *Bothriolepis* and coccosteomorph arthrodires breadthwise growth of the anterior median ventral plates results in the widening of the trunk shield in adults compared to juveniles and subadults. An evolutionary trend in placoderms, and considered a paedomorphic

characteristic, is a shortening of the trunk shield. Studies on arthrodires from the Gogo Formation show that dissociated heterochrony (Trinajstić and McNamara 1999), where both paedomorphic and perimorphic changes occur simultaneously in the one organism, are important for evolutionary change. Perimorphic changes in the rostral plate, the most anterior plate of the head shield in the camuropiscids, has resulted in an elongation of this plate with the most derived members possessing an anteriorly extending tubular rostral plate. The ancestral condition being a T-shaped rostral flush with the pre-orbital plates at the front of the skull roof. Dissociated heterochrony means that each plate could follow its own ontogenetic trajectory resulting in a wide range of body architectures which natural selection could act on. The diversity and disparity of body shapes suggests that heterochrony had a significant effect in the evolution of placoderm morphologies.

## Habitat

During the Devonian, placoderms were the dominant jawed vertebrates, reaching their maximum diversity in the Frasnian stage with the early Devonian representing the first major radiation of jawed vertebrates. Placoderm fossils are known from all aquatic environments and were the first jawed vertebrates to inhabit freshwater systems and open marine waters.

The majority of arthrodires were marine dwellers, had streamline body forms, and were mostly active predators functioning in the nektonic zone. Like modern ecosystems, where faunal diversity is highest in equatorial regions, the most diverse placoderm faunas are from tropical reefs formed at low palaeolatitudes. Faunas from Burranjuk, New South Wales, and Gogo, Western Australia; Australia represent some of the most diverse faunas known in the Devonian. The smaller arthrodires, such as *Compagopsicis* and *Incisoscutum* are found in large numbers suggesting that they formed schools. Other coccosteomorph arthrodires such as *Tubonasmus* and *Rolfosteus* from the Gogo Reefs in Western Australia had compressiform body, adapted for

quick bursts of speed over short distances between the stromatolites and stromatoporoids which comprised the Gogo Reef margins.

Some of the larger arthrodires such as *Eastmanosteus* and *Dunkleosteus* had an extensive adaptive range across tropical and temperate waters. The fusiform body shape represented an adaptation for fast swimming in open pelagic water. These fish were suited to wide dispersal with fossils from these genera known through North America and across the Middle East and North Africa.

Ptyctodonts were also marine dwellers with a globiform body shape which, coupled with their large eyes and thin scleral plates, are indicative of them being slow moving, deep water inhabitants. Low numbers of ptyctodont fossils compared with arthrodires from the same horizons suggest these were more solitary fishes.

The estuarine Miguasha fauna from Quebec is dominated by *Bothriolepis* with only a single genus of arthrodire recovered (Cloutier et al. 2009). Large numbers of *Bothriolepis* also occur in Canowindra, Australia (Johanson 1998), in association with only two other placoderm genera, *Remingolepis* and *Groenlandaspis*. The environment these fossils were recovered from is interpreted as a shallow, freshwater pool, which had dried up. *Bothriolepis* was interpreted as a fresh water fish; however, its presence in the estuarine sediments such as Miguasha and the cold water Witpoort Formation in South Africa, indicated that *Bothriolepis* was anadromous, living their adult life in marine waters and returning to freshwater habitat to breed. However, ontogenetic series of *Bothriolepis* are known from the fully marine Gogo Formation and a mass mortality nursery site from an estuarine environment in the Catskill Formation of North America (Downs et al. 2011). A high paleolatitude nursery site, also interpreted as estuarine and containing fossils of *Bothriolepis* hatchlings, occurs in the Witpoort Formation in South Africa. The occurrence of both hatchlings and juveniles in marine and estuarine environments does not support an anadromous life history strategy for *Bothriolepis*.

Reference to different body morphologies can permit inferences regarding different

locomotor styles present in placoderms (Young 2010). The dorsoventrally flattened body shape, the terminal mouth and anterodorsal eyes of the antiarchs, rhenanids, phyllolepid and petalichthyids indicated that these were bottom dwellers. The rhenanids had enlarged, semicircular ray-like pectoral fins which, and they either undulated or oscillated to achieve propulsion. Phyllolepid arthrodires are found predominantly in low energy freshwater and/or fluvial systems, although there is evidence of them inhabiting estuarine conditions. Although dorsoventrally flattened, it is thought that these fishes were ambush predators, using their long tail to gain rapid burst of speed to capture and swallow prey whole.

## Conclusion

Placoderms were the dominant jawed vertebrates for over 70 million years. They showed both species diversity and morphological disparity, which indicates a great diversity of ecological niche occupation and life history strategies. Historically most placoderms were considered to be slow moving benthic organisms, but re-evaluation of their biomechanics instead reveals that placoderms had diverse modes of life with the most diverse taxa; the arthrodires interpreted as nektonic inhabiting predators.

## Placoderm Morphology

Kate Trinajstić and Kate Roelofs  
Molecular and Life Sciences, Curtin University,  
Perth, WA, Australia

### Synonyms

[Armoured fish](#)

### Definition

Extinct jawed fish in which the head and thorax were covered by bony plates.

### Introduction

Placoderms were a diverse class of armoured fishes, which are thought to have had their origin in the Ordovician Period (~485MYA), although the first fossils are from the Silurian Period (~443.8 MYA). Maximum diversity was reached during the Devonian, when they dominated the earth's aquatic habitats (fresh, estuarine, and marine waters). The Devonian mass extinction event resulted in a great reduction in the diversity of placoderms, although there was some diversification in fresh water forms; however, the reprieve was short lived and all placoderms were extinct by the end of the Devonian Period (~358.9MYA) (Janvier 1996; Young 2010).

The placoderms are the earliest gnathostomes (jawed vertebrates) and are placed at the top of the gnathostome stem, as the sister group

to all other gnathostomes. However, whether placoderms are monophyletic or paraphyletic remains contentious. The most recent phylogenetic hypothesis support placoderms as a monophyletic class comprising eight established orders: Antiarchi, Petalichthyida, Phyllolepidi, Ptyctodontida, Brindabellaspida, Rhenanida, Acanthostroaci, and Arthrodira (Qiao et al. 2016; Fig. 1). The inclusion of another two orders, Stensioellida and Pseudopetalichthyida, within the class remains problematic. The Silurian placoderms *Entelognathus* and *Qilinyu* from China are classed as order *incertae sedis* having some features of primitive placoderms while possessing an osteichthyan type jaw (Zhu et al. 2013, 2016). Placoderms are informative to the study of jawed vertebrate evolution, showing that extant-jawed vertebrates exhibit a mosaic of primitive and derived characters.

### External Morphology

Placoderms are characterised by having the head and thorax covered by bony plates (Fig. 2) and, in some taxa, the posterior section of the body and tail were covered in scales. The robust nature and excellent preservation of the dermal plates means that the shape of the head and thoracic regions is well known for all placoderm taxa, which show a great diversity of body shapes. The antiarchs, rhenanids, phyllolepidi, and petalichthyids are characterized by being dorsoventrally flattened, whereas the Ptyctodontida have a globiform shape and Brindabellaspida, Acanthostroaci, and Arthrodira species vary between dorsoventrally flattened, compressiform, and fusiform (Young 2010).

Placoderms possess paired pectoral and pelvic fins with girdles, although some taxa have lost their pelvic fins. A short-based fin with narrow articulation appears to be the ancestral condition in placoderms for both the pectoral and pelvic fins. In the more advanced arthrodirids, the fin base has extended and a wide-based fin which is multibasal is present. There is single dorsal fin in antiarchs and arthrodirids and two dorsal fins in ptyctodonts

**Placoderm Morphology, Fig. 1** Placoderm phylogeny showing the relationships between placoderm groups and other gnathostomes. (Adapted from Long et al. 2015; Qiao et al. 2016)

whereas the dorsal fin has been lost in rhenanids. The tail, when known, is epicercal.

**Dermal Skeleton**

All placoderms have the head and thorax covered in plates of dermal bone (Fig. 2), which in life were thought to be covered in skin (Fig. 3). The dermal plates of the head shield comprise the skull roof, which was fused to the top of the braincase, and the cheek unit, which posteriorly covered the gill chamber and functioned as an operculum. The jaw cartilages attached to the cheek plates. A dermal neck joint connected the head and trunk shields. The trunk shield encircled the anterior portion of the body and in some forms

enclosed the pectoral fin. In more primitive taxa, external dermal plates form part of the pelvic girdle, separate from and posterior to the thoracic armour. In some species, fin spines are present in front of the pectoral and dorsal fins (Young 2010).

The dermal bone that made up the armour comprised three highly vascularized layers: a superficial lamellar layer, a spongy cancellous layer, and a compact basal layer of lamellar bone (Giles et al. 2013). Embryos show that a base of lamellar bone was laid down first and then an open weave network of spongy bone was deposited over the base. The outer layer is often ornamented, with a series of ridges and/or tubercles made of semidentine. The dermal bone bore the sensory line system housed in open grooves or pits on the surface of the bone.

## Internal Axial Skeleton

The internal skeleton, where known, comprises an external layer of perichondral bone with a cartilaginous core (Janvier 1996). The thinly laminated acellular bone that lines the braincase and nerve canals in primitive placoderms is entirely formed of cartilage in the later placoderms from the Gogo Formation. The placoderm vertebral column comprises separate neural and haemal arches comprising an external layer of perichondral bone surrounding a cartilage core and is the earliest example of a specialized vertebral column in gnathostomes. The anterior portion of the column comprises a series of fused anterior vertebrae, the synarcual, and separate thoracic, abdominal, and caudal vertebrae. The vertebrae under the median dorsal plate do not have neural or haemal spines developed; the haemal spine develops only in more posterior vertebrae; however, neural spines first develop in vertebrae posterior to the median dorsal plate. At the level of the anal fin, the haemal spine is reduced.

## Jaws and Teeth

Within placoderms, the palatoquadrate forms the upper part of the mandibular arch and the Meckels cartilage the lower part (Young 1984). The palatoquadrate is fused to the dermal bones of the cheek, which supports for the jaw articulation along with articulation to the ethmoid ossification of the braincase. In primitive placoderms, the palatoquadrate comprises a single unit, whereas in ptyctodonts, there are three perichondrally ossified elements: the autopalatine, quadrate, and metaterygoid. Placoderms possess two sets of upper tooth plates, the anterior and posterior supragnathals, and a single lower tooth plate, the inferognathal. The anterior supragnathal attaches to ventral surface of the ethmosphenoid regions of the braincase and the posterior supragnathal to the autopalatine. The inferognathal is divided into two sections: the anterior a biting division and the posterior blade. The blade has a groove on the ventral surface where the Meckles cartilage inserts into the inferognathal. The hyoid arch is

less well known as it is rarely preserved. A separate hyomandibular and opercular cartilage has been reported in ptyctodonts and arthrodires (Trinajstić et al. 2012), but the presence of a separate hyomandibular remains contentious. Due to lack of preservation, little is known of the gill arch series posterior to the hyoid arch.

Placoderms have long been considered to lack true teeth; instead, the bony toothplates were considered the wear into shearing blades or grow bony projections that functioned as biting components. The presence of dentine, a dental tissue, has been confirmed in the cusps on the inferognathal in arthrodire placoderms, which also exhibit successional replacement. Further research using synchrotron scanning has revealed, in addition to dentine, the presence of pulp and looped vasculature in teeth of arthrodires thereby confirming the presence of true teeth (Rücklin et al. 2012). The youngest teeth have dentine and an open pulp canal, whereas older teeth are infilled with bone. Placoderm teeth lack a hypermineralized cap common to crown group gnathostome, but it cannot be determined if this is a primitive or derived character state.

## Braincase

All extant vertebrates have a single, fused braincase; however, this is not the case for all placoderms (Young 1986). The braincase in ptyctodonts comprises three (from anterior to posterior) separate units: the ethmoid, orbital, and occipital ossifications, with the ethmoid ossification being the longest of the ossifications (Trinajstić et al. 2012). The general shape of the placoderm braincase is broad and flat. A separate nasal capsule is a primitive character for placoderms and for all jawed vertebrates. A significant reorganization of the head occurs between jawless and jawed fishes. Primitive placoderms such as the antiarchs *Romundina* and *Brindabellaspis* have a short frontal region of the braincase, more similar to the proportions seen in jawless fish, thus placoderms serve to bridge a gap between jawless fishes and crown group gnathostomes in terms of the evolution of the brain anatomy. These early

placoderms also share the character of an upper lip that protrudes well in front of the nasal sacs, also characteristic of the jawless lamprey and osteostracans (Dupret et al. 2014). The early arthrodires provide most of the information known for placoderm braincase morphology as there was extensive perichondral ossification of the braincase, with some of the internal cavities lined with bone, indicating the path of the nerves and vessels. Comparison of the nerve canal lengths between arthrodires and jawless fish shows that arthrodires had much longer nerves suggesting that myelin, a fatty substance used to conduct nerve signals, evolved at the base of the gnathostome stem (Zalc et al. 2007). The optic fissure separates the rostral capsule from the rest of the braincase. The labyrinth cavity of the inner ear is fully enclosed within the braincase and like living jawed vertebrates there are three semicircular canals.

In some placoderms, the sclerotic capsular is perichondrally ossified and muscle scars indicate that the arrangement of the six extraocular eye muscles, which formed antagonistic pairs to move the eyeball (Young 2008; Young et al. 2001). The eyeball is connected to the braincase by a cartilaginous eyestalk, the opening for which is identified behind the optic nerve opening. The orbit is surrounded by five dermal plates, which make up the sclerotic ring.

## Reproductive Structures

Placoderms are sexually dimorphic with many males possessing intromittent elements whereas only the females of more primitive placoderms possessing basal plates. Within the placoderms, the males of three orders (antiarchs, ptyctodonts, and arthrodires) possess an intromittent organ, an external structure used for the transfer of sperm during copulation (Long et al. 2015). These reproductive elements are independent of the pelvic fins (Trinajstić et al. 2015). The presence of intromittent organs indicates that these placoderms reproduced through internal fertilization. In the antiarch *Microbrachus dickii*, as well as all ptyctodonts, the intromittent structures comprise a sheath of external dermal bone with a deep

groove, which may have housed a structure for sperm transfer. The terminal ends of the claspers are often covered in dermal spikes or hooks. Male ptyctodonts also possess paired post-pelvic plates, but these are smaller and flatter than those of females. The intromittent structure of coccosteomorph arthrodires in contrast have an internal support of dermal and perichondral bone, the terminal tip having a small number of dermal denticles.

Within females, external reproductive structures are known for antiarchs and ptyctodonts but not for arthrodires (Long et al. 2015). In female ptyctodonts, paired post pelvic dermal plates curve around the contour of the body; the dermal bone is often ornament with a series of ridges. In one ptyctodont species, *Rhamphodopsis*, females have scales over the pelvic fins, which the males lack. The post pelvic plates were originally thought to have attached to the pelvic fins, but recent work using high resolution microscopy has shown they were separate elements (Trinajstić et al. 2015).

## Musculature

Several regions of life position, three-dimensionally preserved musculature is preserved in some arthrodires is from the Gogo Formation (Trinajstić et al. 2013). The musculature spanning the nuchal gap comprises: large medial paired *capitis* major muscles and smaller lateral *capitis* minor muscles, which functioned as head elevators. The *cucullaris* muscle extends from the base of the skull roof with the origin in the *cucullaris* fossa on the visceral surface of the paranuchal plate and extends onto the upper portion of the anterior dorsolateral plate. Unlike the condition in sharks, where the *cucullaris* muscle functions as a pectoral fin elevator, the *cucullaris* muscle in placoderm functioned as a head depressor. The presence of the *cucullaris* muscle in placoderms represents the phylogenetically oldest occurrence of this muscle, common to all jawed vertebrates. Other cranial muscles that are not as well preserved include the dorsal branchial constrictor muscle, positioned lateral to the *cucullaris* muscle, and the *levator arcus palatini*, a muscle

involved in expanding the mouth cavity for feeding, attached to the postocular process. The preservation of the dermal cheek unit in placoderms, and the perichondral ossification of the quadrate, allow the reconstruction of the adductor muscles, which passed from the lateral side of the Meckels cartilage to the mesial side of the palatoquadrate, a unique condition amongst gnathostomes.

Although the ventral neck musculature is incompletely preserved, synchrotron scans of the shoulder girdle in an arthrodire have revealed the fibers of Sharpey, which indicate where tendons attach muscle to bone. The ventral gill arch depressing muscles in placoderms originate on the interolateral plate (=clavicle). Three separate attachment points on the interolateral plate have been determined to indicate the presence of the *coroacohyoideus*, *coroacoarcularis*, and *coroacomandibularis* muscles between the interolateral plate and lower jaw (Sanchez et al. 2013).

The lateral body musculature is characterized by a metameric arrangement along the length of the long axis of the body, much like in extant fishes. Each vertebra has a short muscle that terminates at the midline of the adjacent vertebra. The architecture of the ventral abdominal muscles, however, is unique for fishes having two anterioposteriorly elongated muscle bands with transversely orientated fibers. The function of these muscles is not fully understood; however the unique presence of claspers, separated from the pelvic fins, and possessing a girdle may have required a unique set of muscles to manipulate them. Another possibility is that these muscles may help resist shear forces between the body armour and the body during swimming.

## Organ Systems

In rare specimens of antiarchs and arthrodires, parts of the soft anatomy are preserved. The infill of the gut indicates that a spiral valve was present and appears to be a primitive characteristic of the vertebrates. Traces of blood vessels can be determined on the trunk armour of *Bothriolepis canadensis*. Although now refuted (Goujet

2011), this vasculature was once interpreted to be associated with lung development.

## Placoderm Classes

### Antiarchs

Antiarchs are second only to arthrodires in terms of species diversity and are perhaps the strangest of the placoderm taxa in terms of body shape. They are also the longest ranging of the placoderms with a continuous record in China from the Silurian to the end Famennian. In east, Gondwana antiarchs range from the Early Devonian and were mostly restricted in Laurussia with the earliest antiarchs not known until the mid-Devonian. This biogeographic difference in the stratigraphic occurrence suggests the origin of the antiarchs is China. Antiarchs are dorsoventrally flattened, the eyes, nares (nasal openings), and pineal opening all occur within the orbital fenestra towards the top of the head. The head shield is closely attached to the trunk shield with the condyles on the paranuchal plate and the fossa on the anterior dorsolateral plate. The body armour comprises two median dorsal plates that extend along the trunk and cover the pectoral fins. The pectoral fins are highly modified; have mid-point ball and socket joint, and a complex specialized joint where the fin joins the pectoral girdle. Primitive antiarchs have short, thick pectoral fins with the body covered in scales whereas in more derived antiarchs the pectoral fins are elongate, and the tail is scaleless. Pelvic fins and a dermal pelvic girdle are known only in the most primitive antiarch *Parayunnanolepis* and are lost in more advanced taxa. Prior to the discovery of *Parayunnanolepis*, it was thought that antiarchs primitively lacked paired pelvic fins. The small eyes and nares occupy a dorsal position in a key-hole shaped opening; the mouth is ventral with highly modified jaws which lack a supragathal and instead the edge of suborbital plate occludes with the inferognathal.

Recent finds of the best-known antiarch, *Bothriolepis*, with the soft anatomy of the tail preserved, show a single, square-shaped dorsal fin, posterior to trunk. Earlier reconstructions

erroneously depict two ovoid-shaped dorsal fins. The shape of the body posterior to the trunk armour is preserved in several specimens. In specimens where the posterior body and tail is covered in scales, the body is stout and tapers to form an epicercal tail whereas in specimens without scales the body tapers to a long whip-like tail.

Males of one species, *Microbrachius dicki*, are known to possess intromittent elements used to introduce sperm into the female (Long et al. 2015). These occur posterior to the thoracic armour and independent of the pelvic fin, which is lost in *Microbrachius*. The intermittent elements vary considerably in size suggesting that they do not appear until sexual maturity has been reached and continue to grow after the body armour has obtained maximum size.

#### **Petalichthyida, Brindabellaspida, and Acanthothoracida**

Outside the antiarchs, the Petalichthyida, Brindabellaspida, Acanthothoracida, Rhenanida, and Ptyctodontida form the non-arthrodire placoderm groups. The relationships of the Brindabellaspida and Acanthothoracida to the antiarchs and other placoderms is not resolved; however, they are considered more primitive than the Rhenanida and Ptyctodontida with the Arthrodire resolved as the most crownward of the Placoderms (King et al. 2016). Petalichthyids have X-shaped sensory line canals on the inner surface of the nuchal plate (also present in ptyctodonts) and two pairs of paranuchal plates (also present in acanthothoracids). They occur in late Silurian rocks in China but have a global range from the early Devonian. The Brindabellaspida are endemic to the early Devonian of eastern Australia. The anterior of the skull is characterized by an elongated rostrum, posteriorly placed orbits, and the unique character of having the nasal capsule housed within the orbit. There is a great deal of intraspecific variation between individuals. The unique morphology of *Brindabellaspis* indicates a specialized ecological niche. The dorsal position of the eye indicates a benthic habitat and the long rostrum with a specialized sensory system, possibly capable of electroreception, could have functioned in the

detection of benthic prey (King et al. 2018). The acanthothoracids are a little-known group due to the generally poor preservation and scarcity of remains. The exception is *Romundina*, which is known from multiple 3D preserved specimens. Re-examination of acanthothoracid collections from the Prague Basin in the Czech Republic have yielded more information, showing them to have a greater diversity than previously thought. The acanthothoracid have a partly tessellated skull-roof and the sensory line canals that run between the plates, rather than through the bone as in other placoderms. They have evolved a flattened body shape, dorsal eyes, and large pectoral fins similar to modern rays and represent the first jawed vertebrates to take up this body morph. The rhenanids differ from other placoderms in that they are covered by unfused platelets with the spaces between the platelets filled by tesserae, which sometime overlay the platelets. The tail and body are covered in scales. The reduction in the size of dermal plates that make up the head and thoracic shields was originally considered to indicate the primitive nature of the rhenanids, but more recently this reduction is considered to be a derived state. The Rhenanida show low species diversity compared with other placoderms and are known from the Early Devonian to the Upper Frasnian.

#### **Ptyctodonts**

The most common fossil remains from ptyctodonts are toothplates, which are known globally throughout Devonian aged rocks. Although body fossils are rare, excellent preservation has yielded a great deal of morphological information. Ptyctodonts are characterized by a reduction in the armour with a number of the dermal plates of the head and trunk shield lost. This frees up the posterior part of the body for increased swimming ability. Ptyctodonts have large eyes, one set of upper (the anterior superognathals are lost) and lower tooth-plates and are the only placoderms known with preserved labial cartilages. Anteriorly Ptyctodonts all have a deep body, one to two dorsal fins, and a long whip like tail. In one taxon, *Campbellodus*, the body and tail are covered in large, oblong scales, which is

considered primitive for this group. The shoulder girdle and pelvic girdle comprise external dermal plates and internal perichondral elements. Both the pectoral and pelvic fins were wide based with two to three basals.

### Arthrodira

The arthrodira are the most speciose and diverse group within the placoderms and are known globally from the early Devonian to the end Famennian. There are reports of earlier (Silurian) occurrences of arthrodira in China but the identification of these taxa as true arthrodira is controversial. Arthrodira are characterized by possessing a specialized moveable neck joint between the head and trunk armours with the condyle present on the anterior dorsolateral plates and the fossa on the paranuchal plate. The excellent preservation of some specimens has provided a wealth of information for both their external and internal morphology. The arthrodira are divided into a number of subgroups.

The Phyllolepidi are characterized by a rounded flat skull with radiating sensory canals. The lack of orbital embayments lead to the suggestion these placoderms were blind (Long 1984). The nuchal plate is elongate and the tail is proportionally long. Their occurrence is restricted to east Gondwana throughout the Devonian. It was only after the Frasnian/Famennian mass extinction event that the phyllolepidi reached their maximum diversity with their biogeographic range extending into Laurussia.

*Groenlandaspis*, so called because it was first found in Greenland, is now found globally and belongs to phlyctaenid subgroup of arthrodira. These arthrodira are characterized by having a high, spine-like median dorsal plate. Specimens of *Africanaspis* have, in addition to the head and thoracic armour preserved, impressions of the body, tail, and fin outlines. This provides an excellent example of the external morphology, showing a short deep body that tapers caudally to form a long whip like tail and a short-wide pectoral fin positioned behind a long serrated spinal plate (Gess and Trinajstić 2017).

Nearly 60% of known arthrodira are eubrachythoracid arthrodira (Young 2004).

They are characterized by shortened body armour connected to the head shield by a lateral ball and socket joint, and in the more derived arthrodira, the pectoral fin is no longer enclosed by the trunk armour and the spinal plate is lost. These modifications are thought to have increased swimming speed and manoeuvrability. The eyes occur further back in the head shield than in earlier groups, where they are set more anteriorly, and the inferognathal comprises an anterior biting division and a posterior blade.

*Coccosteus* from the Old Red Sandstone is often used as the archetypal arthrodire. It is known throughout Europe, North America, and the United Kingdom and is very common in early to mid-Devonian rocks. It has a characteristic arrangement of head shield plates and reduced body armour, the trunk armour encloses the base of the pectoral fin, and there is a spinal plate. The posterior skeleton of *Coccosteus* is known and shows an unrestricted notochord, with paired neural and haemal vertebral elements. *Coccosteus* was an active predator; jaw opening was achieved by moving the head upwards thereby dropping the lower jaws. The distance between the posterior margin of the nuchal plates and the anterior margin of the median dorsal plate, the nuchal gap, determined the gape in the eubrachythoracid arthrodira. Although most arthrodira were between 20 and 50 cm in length, some such as *Titanichthys* are estimated to have reached up to 7 m in length.

### Entelognathus

The position of *Entelognathus* and other maxillate placoderms from the Silurian of China is unresolved. Recent phylogenetic analysis has concluded that most of the uncertainty around relationships at the base of gnathostome tree can be attributed to the maxillate placoderms (King et al. 2016). These placoderms lack the joint between the head and trunk armour and thus the nuchal gap. The trunk armour is elongate, extensively covering the trunk region of the animal. The gnathal plates comprise the maxilla,

premaxilla, and dentary and the adductor muscle both on the lateral and medial side of the palatoquadrate (Zhu et al. 2013). A condition intermediate with crown gnathostome in which the adductor muscle is lateral to the palatoquadrate and other placoderms, the adductor muscle is medial to the jaw.

## Placodermi Diet

## Synonyms

[Armored fish](#)

## Definition

Placoderm diet describes the food consumed for species within the order Placodermi, which includes antiarchs, ptyctodonts, and arthrodires.

## Introduction

There are few cases where the diet of placoderms can be observed directly from preserved stomach contents. Most inferences about diet are made from the type of tooth plates present, calculations of gape and bite force, and body morphology. In addition, the fauna associated with the placoderms can provide information of the food sources available.

The antiarch placoderms (Fig. 1a) are interpreted as being benthophagous. Direct evidence from the gut contents of *Bothriolepis canadensis* from the Escuminac Formation, Canada shows that it fed at on the conchostracan *Asmusia membranacea*. Juvenile specimens of actinolepids have been recovered from Lode Quarry in Latvia with stomachs filled with these small crustaceans, supporting them as secondary consumers (Upeniec 2001). This differs from earlier

interpretations where sediment infill preserving the gut of *Bothriolepis* was interpreted as indicative of these fishes being detritivores, feeding on the substratum associated with plants.

All known Ptyctodont fishes have either durophagous (crushing) or sectorial tooth plates (Fig. 1b), and so the diet is considered as either hard-shelled organisms for the former and soft organisms for the latter. All complete Ptyctodonts known were around 20 cm in length with a small gape, estimated to be only able to take prey with an upper size range of 2–3 cm. Only one ptyctodont from the Gogo Formation (*Austroptyctodus*) has been recovered with stomach contents and these comprise the carapace of ostracods, small crustaceans that make up a component of the zooplankton. Other prey that durophagous ptyctodonts could have fed on, include brachiopods, crinoids, and ammonoids – all of which are found in the same environment as ptyctodonts.

Arthrodires were the most diverse group of placoderms and as such exhibited diverse feeding strategies and diets (Anderson and Westneat 2009). Studies on the jaw mechanics (Anderson 2009) divided arthrodires into three main feeding groups: crushers/chompers, generalists, as well as biters and graspers. Examination of the tooth plates adds another feeding group, the filter-feeding planktivores.

*Holonema* is one of the more perplexing arthrodire fishes, with strange, ridged tooth plates. *Holonema* may have been a filter feeder using the ridged tooth plates to filter zooplankton from the water. However, one specimen from the Gogo Formation has been recovered with stones in the gut region, possibly gastroliths for breaking up oncoids (Miles 1971). Some large arthrodires such as *Homosteus* and *Titanichthyes*, which reached 10 m in length, are also thought to have been a planktivores based on the long thin inferognathals (lower tooth plates).

The combination of shearing bladed teeth (Fig. 1c) a fast opening action of the jaws and a bite strength calculated as stronger than that of the dinosaur *Tyrannosaurus rex* when closing the jaw, and with an estimated maximum size of 6 m, indicates that *Dunkleosteus* was one of apex

**Placodermi Diet, Fig. 1** Examples of tooth plate morphologies found in antiarch, ptyctodont, and arthrodire placoderms. (a) Reconstruction of *Bothriolepis* (after Young and Zhang 1996); (b) sectorial tooth plates present

in Ptyctodonts such as *Kimbryanodus* (after Trinajstić and Long 2009); (c) large shearing bladed tooth plates of the arthrodire *Dunkleosteus*

predators of the Late Devonian (Anderson 2009). No stomach contents are known, but teeth from a shark *Orodus* have been found associated with *Dunkleosteus*, which have been interpreted as stomach contents (Carr and Jackson 2010). The majority of fishes from the Cleveland shale fit into the choppers and crushers feeding guild. Faunal analyses of the fossils from the Cleveland Shale indicate that most taxa were piscivores, with the prey determined by the gape of the mouth. Fossilized concretions comprising fish bones are thought to have been regurgitated by arthrodire and support this piscivorous diet (Anderson 2008). The placoderm *Holdenius*, from the Cleveland Shale, was found with a ctenacanthid shark spine imbedded in its braincase and has been interpreted that the spine penetrated the skull roof as the placoderm attempted to consume it. Some arthrodire from the Gogo Formation also fit within this feeding guild. *Eastmanosteus*, although smaller in size than *Dunkleosteus*, at a maximum size of approximately 1.5 m is the largest placoderm from the Gogo Formation and with similar shaped teeth and jaw proportions is also interpreted as a piscivore predator. Another arthrodire from Russia has been found with a ptyctodont (*Ctenurella*) within the stomach region supporting the interpretation. Arthrodire within the chopper and crushers feeding guild also include species with a durophagous dentition. The toothplate are broad and the blade of the lower jaw is deep, allowing a strong bite force to penetrate hard outer shells or armor. The dome-shaped

teeth that cover the upper tooth plates and the broad lower toothplate in *Bullerichthyes* would have acted like a mortar and pestle to grind up hard prey items before swallowing.

A large number of arthrodire fall into the biters; these are generally smaller arthrodire, up to 30 cm in length, and have small sharp teeth along the upper and lower tooth plates. Analyses of the jaw mechanics indicates arthrodire jaws acted in a scissor like-cutting fashion (Anderson and Westneat 2009). Bite marks on crinoid ossicles from Poland match the tooth plates of coccosteid arthrodire. Stomach contents of *Coccosteus cuspidatus* contain the remains of acathodians and lungfish bones. These smaller placoderms probably fed on free swimming arthropods, ammonoids, and other fishes including smaller placoderms. Some coccosteid type placoderms were originally thought to have been cannibalistic, with young of the same species found in the abdominal cavities; however, it is now known that these represented embryos, yet to be born (Long et al. 2009).

A final group among the arthrodire was the pickers and graspers. These fish have rather weak jaws with little mechanical advantage; the lower tooth plates are slender and lack teeth. Arthrodire such as *Latocamurus* and *Tubonasus* fit within these groups of small, approximately 10 cm long, predatory rapid biters. Their prey were likely small free-swimming, soft organisms that required little processing, being swallowed whole. Not all dorsoventrally flattened fish are

benthic feeders. The very long tail found in the phyllolepis suggests that *Cowralepis* was an ambush predator. The structure of the gill arches shows that a buccal pump mechanism allowed for forcing whole prey within the mouth, probably to be swallowed whole.

Little is known about the diet of the other classes of placoderms, especially in taxa in which tooth plates are not known. The long snouted brindabellaspids are thought to have used electroreception to find prey in the bottom sediments (King et al. 2018), but it is not known if this was hard or soft infauna. The large number of placoderms living in freshwater environments towards the end of the Devonian Period suggests at least some of these were plant eaters but until further evidence is recovered in terms of well-preserved tooth plates or stomach contents the diets of most placoderms will remain unknown. Despite this, placoderms evolved a number of different tooth types and body types to take advantage of different prey items available and divide their environment into specialized feeding niches (Anderson 2008).

Armored fish locomotion

## Definition

Movement used by armored fish to traverse their environment.

Placodermi is comprised of an extinct group of primitive jawed fishes that existed primarily throughout the Devonian Period (416 million–359 million years ago) (Young 2010). As a highly diverse fish group, placoderms were found in many freshwater and marine environments on every continent except South America. The Placodermi receive their name from their characteristic dermal skeleton which formed a head and thoracic shield, allowing them to survive and flourish as into the dominant vertebrates of the time. Over 200 genera of Placoderms evolved between the early Silurian and the end of the Devonian, with the vast majority restricted to the Devonian period. It should be noted that there is considerable debate regarding the phylogenetic relatedness of the placoderms. The earliest were equipped with bony armor plates and adapted to bottom dwelling conditions (Young 2010). Other forms became specialized for fast swimming, traversing open seas. Despite their well-equipped armor and success during the Devonian period, these jawed vertebrates were eliminated during the mass Devonian extinction event.

Nine placoderm subgroups have been identified through observation of skull patterns and morphological features (Young 2010). This chapter will focus on the primary groups and their modes of locomotion. The arthrodires, a major group of the Placodermi, flourished during the Devonian period in various marine environments. They were distinguished by pairs of plates extending from their upper jaw, and a movable joint between the head and body armor (Ferrón et al. 2017). This group produced some of the largest predators of the time such as *Dunkleosteus*, which could measure up to 8 m in length. Most arthrodires were heavily armored and bottom-dwelling with a few evolving into adept swimmers.

Antiarchi were some of the first discovered Placoderms described in 1839 and originally thought to be the remains of tortoises (Young 2010). *Pteryichthyodes* and *Bothriolepis* are two well-known members of this group. Antiarchs were widely spread during the Middle to Late

Devonian. They are best described by their stout thoracic dermal armor and uniquely jointed pectoral fin, encased in armor. Though the purpose of the armored pectoral fin is not certain, Antiarchi were thought to be bottom-dwelling organisms.

Phyllolepidi were a freshwater benthic group of Placodermi characterized by their flattened body, large bony plates, and small eyes on the lateral surface of the head, these organisms were thought to be blind but had excellent sensory perception allowing them to be effective predators. In contrast to the large bony plates of Phyllolepidi, the Acanthothoraci were a group of placoderms that had large scales and plates. This group is unique from other placoderms due to its unusual dermal plate distribution in the skull roof (Olive et al., 2011). Lastly, Rhenanida consisted of flat, ray-like vertebrates with armor made up of unfused scales and tubercles (Fig. 1). These organisms were bottom dwelling predators whose body plan is well documented through fossils of *Gemuendina stuetzi* (Young 2010).

While the placoderms have been well-studied, much uncertainty remains regarding the placoderms' evolutionary history as well as their relationship to the two major extant groups of gnathostomes (jawed fish) (Young 2010). Our understanding of placoderm diversity and evolution is limited by a rather incomplete fossil record. More specifically, much of the research on placoderms describes arthrodires, the most diverse subgroup that dominated the Middle to Late Devonian period. However, this represents roughly half of the ~70 million-year evolutionary history of the placoderms (Young 2010). Recent evidence of Early Silurian placoderms found in China provide new insight into the complex evolutionary history. Additionally, technological improvements in molecular and developmental biology continue to expand our knowledge of the evolutionary history of placoderm diversity and can help us to better understand changes and discrepancies that occurred in a critical period in earth's history.

Anatomically, placoderms are best distinguished by their dermal armor (interlocking

**Placodermi Locomotion, Fig. 1** Various placoderm exemplars: (a) *Dunkleosteus*, an Arthrodire; (b) *Antiarcha*; (c) *Phyllolepidia*; (d) *Rhenanida*

bony plates). The well-preserved dermal bones greatly contribute to fossil remains; however, these dermal plates were often limited to the cephalo-thoracic (anterior body) region (Ferrón et al. 2017). Consequently, the fossil record provides little information regarding the whole external anatomy of these species. With limited knowledge of post thoracic regions, the size and general body shape of many placoderms remains uncertain. Previous reconstructions of placoderms often focused solely on phylogenetically related taxa and did not consider the functional morphology of biological structures (Ferrón et al. 2017). Both body shape and fin shape heavily influence the mode of life in aquatic species, as functional constraints often play a crucial role in types of locomotion and must be considered when discussing locomotor patterns in placoderms. Advancements in 3D technology and digital manipulation of these novel models lend for a more realistic reconstruction of the whole body of placoderm fish (Bécharé et al. 2014).

### Representative Locomotor Behavior of *Dunkleosteus* and *Bothriolepis*

Placoderm locomotion has largely been believed to be anguilliform, with organisms displaying a similar style of swimming to eels. However, genera from two of the major groups of Placodermi demonstrate differences in swimming modes and niche. This section will examine the two most significant modes of locomotion employed by *Dunkleosteus* and *Bothriolepis*.

*Dunkleosteus* is a genus of the extinct arthrodire that dominated the seas during the Late Devonian period. Approximately 10 species have been documented, with *D. terrelli* being the largest and most well-studied. These vertebrates could grow up to 8 m and possessed sharp bladed jaws that enabled them to thrive as carnivorous predators (Carr 2008). However, the lack of preserved remains of these arthrodire have made complete reconstruction difficult. Previous inferences regarding the size and body plan have been

drawn from fossil records of *Coccosteus*, a separate genus of arthrodire (Ferrón et al. 2017).

Placoderm paleoecology research suggests that most species were benthic, however, an analysis by Carr (2008) suggests that *D. terrelli* was a pelagic organism. This means that *Dunkleosteus* would have traversed the open seas in environments that may have been unfavorable to other Placoderms. The discovery of ceratotrichia, stiff filaments resembling keratin, in a pectoral fin of *Dunkleosteus terrelli* points toward the idea that placoderm fins had a greater range of variability and locomotor capabilities than previously thought (Carr et al. 2010). To further understand its locomotion pattern, we can turn to modern day sharks as models. Both organisms have similarities regarding body plan and function. *Dunkleosteus terrelli* was believed to have been a strong swimmer that employed use of pectoral fins as glide planes for more efficient locomotion (Barron and Etness 1981). Like sharks, *Dunkleosteus* may have swam using body-caudal fin propulsion, thereby generating thrust using lateral tail movements (Ferrón et al. 2017). It has also been proposed that *D. terrelli* used anguilliform propulsion which is normally characteristic of eels. However, this seems unlikely due to limitations in lateral movement of the head and trunk by the cephalic shield (Ferrón et al. 2017).

*Bothriolepis canadensis* was a Late Devonian placoderm species found in eastern Canada. More than 60 species of *Bothriolepis* have been identified, although *Bothriolepis canadensis* is historically considered to be the most well-known (Bécharde et al. 2014). *Bothriolepis* belong to the Antiarchi, which first appeared in China in the Silurian age. Antiarchs remained relatively stable throughout the Early Devonian age and reached their peak diversification in the Middle to Late Devonian ages (Young 2010). Antiarchi are distinguished from other Placoderms through pectoral spines that are covered with dermal plates. While the pectoral fins of early antiarch species were short and thick box-like structures, the pectoral fins of more advanced antiarchs, including the *Bothriolepis*, were long and jointed and loosely resembled the limb of an arthropod

(Liem et al. 2001). The function of these jointed pectoral spines still remains unknown, although numerous hypotheses indicate that they may have been used for swimming maneuverability, to elevate the body, to hold the body stationary in flowing water, or to help pull them across the ocean floor during bottom dwelling walking (Liem et al. 2001).

Locomotion in the aquatic environment is largely dependent upon the underlying functional anatomy of an organism. Despite being considered one of the best-known species, new analysis of the *Bothriolepis canadensis* suggests that prior reconstructions were anatomically inaccurate. As a result, previous hypotheses regarding the mobility of the cephalad armor, submarginal plates, and pectoral fins were based on the misinterpreted external anatomy (Bécharde et al. 2014). This confusion contributed to the idea that some late *Bothriolepis* species may have developed morphological specializations that made swimming an effective mode of locomotion.

*Bothriolepis* is believed to have been a sluggish bottom-dwelling fish that exhibited primitive patterns of locomotion. It is likely that these species remained closely associated with the seabed because they were unable to support themselves in the water, overcome frictional and other forces, maintain stability, or maneuver through the dense water (Bécharde et al. 2014).

Due to the confusion regarding the morphologic features of the *Bothriolepis*, current research on *Bothriolepis* movement focuses on anatomical limitations that suggest that swimming was not a feasible mode of locomotion. There are several requirements that make swimming possible in aquatic organisms. First, a swimming animal must have the ability to support itself in water. An object in fluid displaces a weight of fluid that is equal to its own weight. The fluid that is displaced will exert an upward force on the object (Liem et al. 2001). When an object is placed in water, this upward force is substantial because water is dense when compared with air, resulting in considerable buoyancy. Buoyancy is the major force that supports a fish; however, the weight of a fish slightly exceeds the upward buoyancy force because flesh including bone and muscle have

densities greater than the surrounding water (Liem et al. 2001). Thus, for a fish to swim it must be capable of generating a lift force that can overcome the downward pull of gravity. Heavily armored early fishes including *Bothriolepis* and *Dunkleosteus* exhibit negative buoyancy and consequently swimming would be very costly. Even if the *Bothriolepis* was able to support itself in water, for it to be capable of swimming it would also have to overcome drag forces (i.e., a combination of substantial frictional and pressure forces that provide resistance to movement through a medium) (Liem et al. 2001). Finally, most fish that swim generate propulsive forces using undulatory movements or bends of their bodies that move caudally from trunk to tail. As these undulatory movements travel back, they create lateral and forward thrust forces that propel the fish forward and oppose the drag forces (Liem et al. 2001). Recent analysis showed it is unlikely that the caudal fin of *Bothriolepis* could generate these propulsive forces (Bécharé et al. 2014).

## Evolutionary Implications of the Placoderms

Placoderm are members of the larger group known as gnathostomes, defined as jawed vertebrates. Hinged jaws were a pivotal evolutionary adaptation as they allowed organisms to have a fast, active, and controlled bite. From ancestral gnathostomes evolved two major divisions, the chondrichthyans, or cartilaginous fish that includes modern day sharks and rays, and the osteichthyans, or bony fish which gave rise to all terrestrial vertebrates. Placoderms were always considered a sister group of the gnathostome stem, thus suggesting their bony structure evolved independently of osteichthyans. It was previously hypothesized that the common ancestor of chondrichthyans and osteichthyans resembled a cartilaginous shark and that bony fish were a specialization from this ancestral state (Friedman and Brazeau 2013). However, discovery of a 419 million-year-old fossil in China had rebuked this hypothesis (Zhu et al. 2013). The fossil, *Entelognathus primordialis* resembled a

placoderm, with bony armor and jaws. From this discovery a new hypothesis emerged suggesting that cartilaginous fish were a unique adaptation, losing their bony skull and jaw, the primitive feature.

## Conclusion

In this chapter, we have explored the locomotive patterns of the extinct placoderm vertebrates. There has been some debate regarding swimming behavior and niches with many believing that most placoderms were bottom-dwelling and sluggish in movement. The lack of preserved fossil specimens has made it challenging to reconstruct full body models, requiring inferences to be made based on modern day sharks. However, examination of placoderm anatomy has yielded information pointing to differences among the subgroups, affecting our previous understanding of locomotion within these organisms. This is best evidenced by *Dunkleosteus* and *Bothriolepis*, members of the two most significant subgroups. Further research and exploration is needed to obtain a more in-depth knowledge of Placoderms and their domination of the seas millions of years ago.

### What Is Planning? Why Is It Important?

Thinking about the future is a common human behavior. Whether one is anticipating an opponent's move and one's subsequent response in a game of chess, or simply making a plan to pick up milk on the way home from work, the future is something we think about nearly every day. However, the cognitive mechanisms that underlie future-oriented thinking, or prospective cognition, are as complicated as the future itself. Szpunar et al. (2016) have divided prospective cognition into four main modes of future thinking: simulation, prediction, intention, and planning. There is an intersectional relationship between all four modes, but planning is arguably the one that most integrates the other three. One definition of planning is the predetermination of a course of action aimed at achieving a particular goal (Hayes-Roth and Hayes-Roth 1979). Another is that planning requires an individual to predict a future event, simulate the circumstances of and reactions to that event, and set an intention of what to do when the event occurs (Szpunar et al. 2016). A simpler definition comes from Miller et al. (1960): a plan is a hierarchical process that controls the order of sequence of operations. Immediately, one sees that there is not consensus on what we mean by the term planning before we even get to the question of whether animals engage in planning. Our position is that there is extensive evidence of animals engaging in planning as per Miller et al. and Hayes-Roth and Hayes-Roth, and rarer, suggestive evidence of such planning as per Szpunar et al. In the case of “planning as sequencing,” there does not need to be a distant future goal, and planning can involve the structuring of a response or sequence of

responses right before they are made. In the “planning as simulation and prediction” definition, there is greater demand on prospective cognitive faculties that could include so-called mental time travel and the ability to anticipate oneself as being in a different state in the future than one is in at the present.

The question of whether other animals are capable of planning sometimes has been controversial, in part because of these varying definitions of planning. Our goal is to describe some of the forms of planning that have been assessed in nonhuman species and what has been found in those tests. The presentation order is perhaps reflective of a hierarchy of less sophisticated to more sophisticated forms of planning, although we caution the reader that one should not assume that this is a progression through which evolutionary emergence of human planning occurred, or even that this hierarchy could be used to assess a species’ “planning capacity.” Rather, we believe that these are all instances of future-oriented behavior that can be called planning, and that reflect the need for organisms to engage different mechanisms to organize behavior in ways that afford goal attainment.

## Motor Planning and Sequence Planning

Motor planning refers to generated behavior that anticipates how an action will generate an optimal end state for the physical movement that is performed. For example, humans tend to grasp objects based on how they intend to use them rather than on simple convenience with regards to the orientation of the object. Humans will even adopt uncomfortable initial positions that lead to comfortable ultimate positions, as when we reach toward an overturned glass with an inverted hand so that the glass can then be rotated into the orientation we need it to be in to use it as designed. Other species also do this. Capuchin monkeys selectively orient their thumbs and hands in ways that allow them to efficiently retrieve food from an object or use that object as a tool (Zander and Judge 2015). Rhesus macaques select efficient grips when transporting spoons that they

use to gather reward (Nelson et al. 2011). Tamarins (Weiss et al. 2007) and lemurs (Chapman et al. 2010) show the end state comfort effect, grasping objects in a less comfortable first contact so that they can end with those objects in a comfortable and efficient-to-use orientation.

Sequence planning in nonhuman animals has typically been assessed using computerized tasks that afford the subject the necessary information to complete a trial correctly, if it can produce the correct sequence of responses. In some cases, those sequences must be planned in advance or else errors will occur. Computerized maze tasks allow assessments of how far ahead through the maze a subject can determine its moves at choice points, and nonhuman primates sometimes can plan for at least one or two future choice points within a computerized maze (e.g., Frigaszy et al. 2009) or other types of mazes (e.g., Volter and Call 2014). Similarly, pigeons were trained to move a target towards a goal in a plus-shaped maze task (Miyata and Fujita 2008). The goal was then shifted one to four moves away from the intersection of the maze. Pigeons showed more errors when the goal change was done closer to the choice location, suggesting that they had planned the route to take to the goal and had less time to acknowledge and compensate for the change. In a more complicated 2D maze task, capuchin monkeys were trained to move a target to a goal with the addition of correct choices that moved away from the goal, and while those completing the mazes in order of increasing difficulty did better than those completing the mazes in random order, they did not show an overall decrease in errors as time went on. However, it should be noted that the difficulty these animals experienced may have stemmed from a lack of experience with the task, as another study showed that capuchins did better on a similar maze task when given more trials (Pan et al. 2011).

Nonhuman primates and pigeons have been trained to sequence stimuli presented on computer screens in a specific order, and then trials are presented in which the stimuli are occluded or manipulated in other ways so that correct completion of the sequence can only happen if the subject has remembered the rest of the sequence that

needs still to be made. For example, pigeons were trained to select three items in sequential order, with a switch and mask condition introduced after training (Sarf and Colombo 2010). The switch condition involved the location of the second and third items being reversed after the selection of the first item, and in the mask condition, the second and third items were covered by an opaque white square after the subject selected the first item. In the switch condition, the latency in responding between the first and second item was higher than that of baseline trials with no items switching locations, suggesting that the birds needed time to readjust a plan created based on the initial location of the items. The mask condition showed that the pigeons performed significantly better than chance, indicating that they had already spatially mapped out the three items and perhaps planned their selection order before they selected the first item and were thus unhindered by the masking of the items. Other studies showed similar results for latency patterns and difficulty with the switch condition and mask condition, suggesting that sequences were planned at most one item ahead (e.g., Beran et al. 2004; Beran and Parrish 2012; Sarf and Colombo 2009), but in some cases, performance was high even for completing sequences of six or more items that are no longer visibly present (Inoue and Matsuzawa 2007; Kawai and Matsuzawa 2000).

### Anticipation of Future Needs and Planning Accordingly

Although it is not controversial that organisms anticipate needs, there is a debate as to whether they can anticipate needs that they *do not presently have but will have later*. The Bischof-Köhler hypothesis states that animals cannot anticipate future states that differ from current states, and therefore cannot plan for a future that is unlike their present. Instead, animal planning abilities are considered to exist only in cases where immediate needs can be satisfied through the production of a sequence of responses to obtain reward (e.g., Suddendorf and Corballis 2007). However, some research challenges this sharp divide between the planning abilities of humans and other animals.

In multiple studies involving a food caching task, different species have shown the ability to selectively cache food based on the availability of different food sources in the future (e.g., Cheke and Clayton 2012; Raby et al. 2007). Specifically, birds chose to cache foods that they learned would not be available in the future even when they were satiated on that food in the present. In a more applied task involving thirst and water access, squirrel monkeys were given the option to choose a smaller amount of thirst-inducing food with the payoff of their water access being restored quickly, or a larger amount of thirst-inducing food which made the wait time for water much higher. The monkeys came to prefer the smaller amount, presumably because they anticipated a later thirst that could not be quenched (Naqshbandi and Roberts 2006). The choice could not have reflected current thirst since water was available at the time of the choice. This result stood in contrast to the behavior of rats that continued to choose the larger food amount even when water was restricted for longer. It also stood in contrast to the performance of rhesus monkeys (Paxton and Hampton 2009). This difference in the choices made by rhesus and squirrel monkeys could stem from their life histories, as squirrel monkeys naturally consume a more water-rich diet than rhesus monkeys. If a more relevant motivator was used, it is possible that rhesus monkeys would display the same behaviors as their New World counterparts. However, it was also possible that training histories and specific previous experiences played a role in choices, suggesting that outcome contingencies may have been as relevant as anticipation of future states.

Apes tend to provide stronger evidence of planning for future conditions, especially in tasks that require use of tools. Generally, these tasks involve the apes learning to use a tool to retrieve an obstructed reward. They are later given the chance to choose from a selection of multiple tools and keep their choice with them until they need it in the future. Apes consistently choose the correct tool without any cueing for the future task or the current need for the tool, directly opposing the Bischof-Köhler hypothesis (Mulcahy and Call 2006). Osvath and Osvath (2008) also

found that, when presented with a set of novel useful and useless tools, apes consistently chose a useful tool even though it could not be used right away. Sometimes, this choice of a good tool *for a later task* was made over an immediate, lower preference reward. In one particularly illustrative case, a chimpanzee collected stones before the arrival of visitors to his zoo exhibit, and then threw those stones at people. These kinds of behaviors may indicate that chimpanzees at least can anticipate future needs and organize current behavior in a manner that gives them access to future rewards (see Osvath and Martin-Ordas 2014).

More recent work suggests that some birds may show similar capacities for this type of choice behavior for items that can only be used later (e.g., Kabadayi and Osvath 2017). However, it is important to note that these tests afford the possibility of success without need of planning. For example, choosing a tool that is more often associated with food over other tools with no such association could be expected to occur even if an animal had no expectation that it would use that tool later, or want food later, or even still have the tool later (see Hampton 2019). It is important to use conditions in which some trials will have a future possibility to use a tool or exchange a collected token, but others will not, so that the tools or tokens themselves are no longer valuable (or invaluable) in all circumstances, but are differentially valuable *based on what is expected in the future*. Tasks that provide these contrasting trial types have shown that some apes can distinguish between those contexts and selectively anticipate the need to choose and retain items that are only valuable later (e.g., Bourjade et al. 2014).

## Prospective Memory

There is a specific type of planning that has, as its focus, the formation and storage of an intended future action. This is called prospective memory, and it consists of four stages: Anticipating a future need, encoding the necessary response to be made when the relevant cue or appropriate time occurs for that response, retrieving that intention, and

implementing that intention. For example, remembering to add birthday candles to your regular grocery store visit next time you need groceries is an example of a prospective memory. Prospective memory is less frequently studied in nonhuman animals, but there is evidence that some species may engage in such future-oriented forms of planning.

Rats show evidence for prospective memory. Wilson and Crystal (2012) trained rats to classify different tones as short or long in duration. The rats also learned that a large meal would be presented at a future time within each session, and the rats showed anticipatory behavior (e.g., they poked their noses into the food trough) right around the correct time of that meal. This suggested they were monitoring the time in the task to be ready for when it was the appropriate time to go eat the meal. This anticipation and monitoring came with a performance cost in the tone discrimination task (Wilson et al. 2013), a result that aligns with the decrements in performances sometimes seen when humans must engage in active monitoring for cues to evoke prospective memories.

Primates also show evidence of prospective memory. For example, a language-trained chimpanzee was given a choice of two preferred foods, and she received the chosen item immediately (Beran et al. 2012). The other item, that was not preferred at that time, was left indoors, while the chimpanzee was moved outdoors where she found other much more highly preferred foods than either indoor item scattered around a large enclosure. She was allowed to obtain those items and then return indoors at will. The key issue was that she could still get the last item but only if she remembered to bring in a specific token that held the symbol associated with that item. Her behavior indicated that she first retrieved the high preference items, and then moved to find the correct token and complete the retrieval of the least preferred item that was available that day. On control trials, with no other item still indoors, she was less likely to retrieve any token. This pattern could only happen if she encoded the item type she *had not selected*, at the start of the trial, and then later spontaneously decided when to search for and retrieve the token with the symbol matching

that item she had earlier rejected. This performance may also challenge the Bischof–Köhler hypothesis, given that she had to remember the name of a thing she valued less than what she had just selected, although it is difficult to design a task for which a present stimulus could truly have no value to an animal at one point and then become valuable later without training those possible states.

## Planning in the Wild

Laboratory studies always carry with them the limitation of their artificial environment, so it is helpful to also test the planning abilities of animals in the wild. Much of this effort has focused on nonhuman primates. For instance, planning behavior may manifest through communicative signals. One example is in the form of vocalizations seen in wild orangutans (van Schaik et al. 2013). Wild male orangutans use long calls to indicate their travel direction during the day, and they may even travel in the direction of calls they produced the night before. Not only do they seemingly plan their travel routes the night before, but other individuals in the area listen to and use this information, with females moving in the same direction as the calls and subordinate males moving in the opposite direction, suggesting that they too understand that the call indicates where the dominant male will be moving in the future.

Chimpanzees may choose their evening nesting sites based on their likely travel destination the next day, which could suggest that they anticipate and even plan to go in those directions (Janmaat et al. 2014). For example, when preferred and fairly infrequent fruits are ripening, chimpanzees sometimes make their evening nests closer toward the locations where those foods are located compared to where they make evening nests when other, less preferred foods are the items that are eaten the next day. They may even choose to rise earlier or later depending on what fruit was ripe and how far away that food was, and this could involve some form of anticipation and plan for the next day's movements

(also see Ban et al. 2014). Monkeys, too, may do these kinds of things (e.g., Noser and Byrne 2006). Of course, it is not certain that these are plans made the night before in the sense of being intentional series of events toward a specific goal the next day. It could instead be more of a feedback loop where nesting sites are made as the animals are in a state of considering a travel direction in general (because it would lead to food, for example), and there is increased chance that they take that direction of travel the next day because of where the nests are located when they awake, and they are reminded of the food in that direction.

Other possible examples of planning by animals in the wild include tool use. Chimpanzees collect nuts and hammer stones, moving those to areas with a suitable “anvil” against which they can crack those nuts (e.g., Boesch and Boesch 1983), and this sequencing of behavior falls perfectly in line with the idea of planning held by Miller et al. (1960). It also matches in character some studies in captivity. For example, chimpanzees have been reported to save tokens to use them in the near future, indicating that they anticipated a delayed opportunity to exchange them for food (Sousa and Matsuzawa 2001), and they learn to trade tokens or real food items in the present so as to obtain something better (e.g., Dufour et al. 2007). It is even possible that the planned hunts that chimpanzees undertake involve some form of planning (e.g., Stanford et al. 1994), although it is difficult to distinguish this from the coordination of behavior as it unfolds in real time among the group of hunters.

Lest one think that non-primates are non-planners, consider a very different kind of animal. Spiders from the salticid subfamily Sparidae prey on other spiders and have evolved complex strategies for targeting and capturing such prey. In some cases, they take detours away from prey that eventually lead them into more ideal vantage points for a successful capture. Laboratory tests that mimic this natural situation involve presenting the subject spider with a tower from which it can see prey, and see paths to that prey but also paths that would not lead to the prey (Cross and Jackson 2016). These spiders took

the correct path, even though it led to loss of sight of the prey and sometimes involved moving past a more direct (but ineffective) path toward the location where prey had been seen. This suggests a planned motor movement pattern with the goal of reaching the prey animal. Whether spiders or other non-primate species can show evidence contrary to the Bischof–Köhler hypothesis is unclear.

## Summary

It is a fair conclusion that nonhuman animals can engage in planning behavior. The evidence seems conclusive that other species can anticipate things that are about to happen in their environments and adjust behavior to accomplish a goal that is not immediately possible to accomplish. It may be the case that such plans are complex in terms of involving sequences of responses that must be implemented in the correct order, and that order must be determined before the task is begun. In some rarer cases, those planned behaviors may be generated in anticipation of a goal that is not physically present, or even a goal that, at present, is not valued (but it will be in the future for that animal). This is a controversial (and exciting) question that requires more work, especially to ensure that there are not alternate explanations of such behaviors that do not require planning (Hampton 2019). Paxton and Hampton (2009) noted that work on planning behavior, especially for the types of planning that are suggested to involve mental time travel, must allow for assessments without the possibility of trial and error learning (see also Suddendorf and Busby 2005). Those tests also need to avoid species-typical behaviors as those may be more reliant on associative learning rather than planning.

Of course, many of these behaviors we have described as being evidence of planning do not have to involve seeing oneself in a future event. It would be premature to conclude that other species have the “autonoetic” aspect of mental time travel that *sometimes* occurs when humans think about and plan for the future. Of course, much of human planning also occurs without need of autonoesis

or any form of conscious anticipation of the future (e.g., adults rarely think about brushing their teeth even though they engage in a highly routinized plan for doing so). So, the question of mental time travel should not be central to any discussion about whether animals can plan at all for the future, although it is an exciting and important type of planning to study. Foundational future-oriented cognitive processes such as motor planning and the structuring of sequences of responses are not reliant on mental time travel, any more than semantic memories of the past are reliant on autonoetic episodic recall. Not knowing how *it feels* to an animal to think about the future and plan for it does not prevent us from taking the perspective that other species are capable of planning for some aspects of their future so that they can organize behavior in a way that affords accomplishing goals in that future.

## Introduction

### What Is Plant Behavior and Cognition?

A mark of intelligent behavior is the capacity to select actions that allow an organism to achieve its goals. Although there is no universally agreed-upon definition of what behavior is, an operational strategy that applies to both plants and animals is to approach behavior in terms of the “observable consequences of the choices a living entity makes in response to external or internal stimuli” (Cvrčková et al. 2016). Such choices, when performed by animals, usually involve movement. Because plants are sessile, it becomes more difficult to appreciate their behavior. But behavior takes place regardless of the mechanism (e.g., muscle contraction vs. cell elongation) that underlies overt plant and animal responses. Laying the stress upon animal, as opposed to plant behavior, becomes a matter of scale and bias. Compare a plant that grows leaves and orients itself toward the sunlight to a sponge that forages for oxygen and nutrients by pumping water through its body. Plant behavior, understood as phenotypic plasticity in response to environmental contingencies, does take place in the form of growth, for instance (Trewavas 2017). Consider, more dramatically, a climbing plant growing up a

tree clinging with its tendrils, twining, and uncoiling around as it forages for light from one tree to the next (Darwin and Darwin 1880).

With regard to cognition, an encompassing biological perspective calls for the manipulation of the environment in order to enable metabolic functioning. This, however, does not entail that all of plant behavior is cognitive. Inflexible, hard-wired reactions to environmental stimuli are not interesting from a cognitive science perspective. Non-hardwired strategies appear to be needed for a behavioral pattern to become cognitive. It is the degree of flexibility that can be observed in the behavioral repertoire of plants as they assess, say, potential conditions under pressure that grants the ascription of intelligence to them (Trewavas 2014). Among other things, the list of competencies includes the capacity to integrate sources of information into flexible overt responses and the capacity to anticipate future contingencies and make decisions accordingly as to how to alter its traits in the phenotype (Novoplansky 2016). More generally, cognition would encompass plant behavioral patterns that are adaptive, flexible, anticipatory, and goal-directed (Calvo 2016), that is, those overt patterns which are functionally analogous to purposeful and intentional animal behavior, as increasingly exposed under time-lapse photography in many documentaries, David Attenborough's style.

## History

### Early Beginnings

The concepts that gave form to the idea of intelligent behavior in plants were already present in the pioneering work of Charles Darwin (1809–1882), Wilhelm Pfeffer (1845–1920), Gottlieb Haberlandt (1854–1945), and Jagdish Chandra Bose (1858–1937), among others. As Darwin foresaw in *The Power of Movement in Plants*, strictly speaking, if there are no “lower” and “higher” species hierarchically ranked on *Scala Naturae*, then botany is not subordinate to zoology. Darwin suspected that some form of electrochemical communication was behind the responses of carnivorous plants. Lacking appropriate experimental

apparatus, he shared his insights with physiologist Sir John Burdon-Sanderson (1828–1905), at University College London, who, after measuring a voltage difference between the upper and lower surfaces of Venus flytrap leaves, was able to characterize action potentials in plants. Pfeffer had likewise envisioned the similarities with the way plants and animals process information. Haberlandt subsequently proposed the phloem as a nerve-like structure that plays a role analogous to the nervous system of animals for the sake of relaying information.

After the discovery of plant action potentials in the 1870s, Bose investigated the electrophysiology of plants in detail, monitoring electrical activity and the transmission of action potentials. As he urged, there is no doubt about the “nervous character of the impulse transmitted to a distance.” Against conventional wisdom, Bose argued that plants had “a system of nerves that constituted a single organised whole.” In 1926 he published *The Nervous Mechanism of Plants*, challenging the norm by using the expression ‘plant nerves’ in his work. Working on the sensitive plant *Mimosa pudica*, Bose showed that leaf folding was likewise triggered electrically as there is “transmission of excitation” between the petiole and the pulvinus that results in loss of turgor and thereby induces folding. In the 1930s plant action potentials were registered by inserting microelectrodes in the giant cells of freshwater algae *Chara* and *Nitella*. This served to unearth the mechanisms of cellular excitability. All this happened before action potentials were first recorded in the squid giant axon. Some decades later, pioneering research conducted by 1963 Nobel Prize winners Alan Lloyd Hodgkin and Andrew Fielding Huxley revealed the three-fold phase profile of animal cell excitability. It happened to hold equally for plant cells, with electrical transmission being an all-or-nothing action potential. Only in the last decade, plant electrical excitation transmission has been comprehensively linked to plant behavior (Baluška et al. 2006).

### Plant Signaling and Behavior

Plant adaptive behavior requires the coordination of physiological needs among the diverse plant

structures. The environment in which plants eke out a living is highly complex, with many vectors, other than light or gravity, to be appropriately navigated. Fine-tuned integration of information signaling across the root and shoot systems to achieve the plants' overall goals is thus needed (Calvo 2016). Electrical signaling plays a central role in integrating the plant body, as we have learned from plant electrophysiology (Volkov 2006). Despite the lack of neural tissue or synaptic connections, all higher plants regulate physiological processes in part by electrical means. The focus on the electrophysiological properties of plant cellular networks has permitted in the last decade to stress the need of a unified account of integrated signaling and adaptive behavior (Baluška et al. 2006) for the purpose of studying plant behavior and cognition.

In particular, plant anatomy and physiology reveals a highly cross-linked phyto-neurological structure akin to the cellular networks of invertebrate nervous systems. The vascular system of plants, initially thought to mediate exclusively the transport of water and nutrients, allows higher plants to coordinate their behaviors, with electric communication taking place over long distances through vascular bundles (Calvo et al. 2017). Plant science is starting to reveal the analogies in the way sets of behaviors in animals and plants get organized. Animal nervous systems were evolutionarily tailored with the purpose of coordinating free-moving behavior and thereby happen to organize signaling systems differently. Overall, research in plant signaling and behavior aims to unearth the particular way in which plants perceive and act in an integrated and purposeful manner, despite their sessile nature.

## Aspects of Plant Cognition

Stripped of anthropocentric interpretations, many features of cognition traditionally taken to be the sole purview of psychology are present in the *Plantae* kingdom. The list of competencies includes competition and foraging and the capacity to communicate, learn, and memorize, among other aspects of cognition (Trewavas 2017).

## Competition and Foraging

Foraging refers to the type of changes in behavior that permit organisms to procure their life-sustaining supply of energy. The term applies to plants insofar as they actively search for light, water, nitrates, phosphates, and other nutrients (Trewavas 2008), selecting the most convenient direction of growth. Resource foraging takes place in highly dynamic and heterogeneous environments, with resources patchily distributed. This requires precise structural changes at the level of morphology, physiology, and phenotype for the sake of optimal energy intake in a context of Darwinian competition. Red/far-red light ratios, for instance, inform plants as to how to grow out of shade and forage more effectively for light.

Competitive foraging takes place in both shoot and root apparatuses. As a result, shoots and roots typically present a branched morphology that allows plants to scan their surroundings more effectively. Leaves, branches, and root tips make decisions on a regular basis, such as accelerating or decelerating their rate of growth along positive or negative resource gradients, be it gradients of light intensity in the case of shoots or gradients of humidity and nutrient concentration, in the case of roots. Optimal foraging requires that all such local information registered at the sensory periphery of the plant body is integrated for the purpose of delivering a global response (De Kroon et al. 2009). Root territoriality, for instance, exploits the geometric structure of the soil itself. This illustrates the need of integration and the idea that the behavior of plants is not guided locally but rather globally.

## Communication

Plants exchange gases on a regular basis. Over one third of the carbon they assimilate is released back into the atmosphere in the form of volatile organic compounds (VOCs). The release of VOCs is not just a by-product of plant physiology. Plants exude them throughout their whole body to “talk” and “listen” to conspecifics and to members of different species (Dicke et al. 2003). Popularized as “talking trees,” or “eavesdropping,” a tree under stress, for instance, can pass along airborne

warning signals, permitting other plants in the vicinity to trigger defense mechanisms ahead of time. Some plants, like *Cuscuta pentagona* (dodder), unable to photosynthesize carbohydrates, rely on VOCs to twine round host plants and suck their nutrients out of their vascular system. *Cuscuta* can discriminate between volatiles exuded from both tomato plants and wheat plants and choose to grow selectively toward one or the other (Runyon et al. 2006).

Communication also takes place underground courtesy of networks of mycorrhizae that allow trees to remain in contact with one another. Symbiotic growth of these fungi with the root apparatus of trees results in patterns of flexible behavior, delivering ultimately overall fitness (Gorzelak et al. 2015).

There are other forms of sensory input that plants can rely on for the purpose of communication. Research in plant bioacoustics (Gagliano et al. 2012) informs us that plants can benefit from the perception of sound and vibrations. The munching of caterpillars results in specific vibrational patterns that plants can detect. *Arabidopsis thaliana* respond by synthesizing toxins to the vibrations produced by munching caterpillars (Appel and Cocroft 2014). Trichomes (hair cells) located on the leaves and stem of *Arabidopsis* respond to mechanical stimulation, acting as acoustic detectors or “mechanical antennae” (Liu et al. 2017).

### Learning and Memory

Plants enhance their foraging behavior for light and nutrients by modifying their behavioral repertoire through learning and memory processes. Although plant learning and memory may be approached at different levels, the field has benefited particularly from the study of learning as practiced by comparative psychologists. Recent research has focused on overt behavior by applying the methodological toolkit of the animal learning literature under neobehaviorist paradigms (Abramson and Chicas-Mosier 2016).

Both nonassociative and associative forms of learning have been documented to take place in plants. Habituation has been observed in members of the carnivorous *Droseraceae* family (sundew)

and *Passiflora gracilis* (passion flower), with reports dating back to Pfeffer and Darwin. The sensitive plant *Mimosa pudica* is the best-studied model for nonassociative learning. The most detailed study to date has been done using *Mimosa* in the context of light foraging and risk predation (Gagliano et al. 2014), having shown that the leaf-folding reflex of *Mimosa* used for the purpose of defense against herbivory habituates after vertically dropping the plant repeatedly. The learned response lasted up to a month.

Habitation is consistent with an instinctual reading of plant behavior and therefore represents the simplest form of learning. More sophisticated forms of learning include Pavlovian classical conditioning. Classical conditioning has been reported more recently in the garden pea *Pisum sativum* (Gagliano et al. 2016), where the direction of growth was affected by a neutral stimulus against the naturally occurring phototropic behavior. Conditioning evidences the acquisition of new competencies that can enhance foraging behavior and, together with nonassociative forms of learning, constitute adaptive processes that point to a basic form of memory.

### Models of Plant Behavior

Plant behavior could involve the processing of information, depending on whether a computational framework is endorsed or not. Until recently, the study of plant behavior was dominated by information-processing assumptions incorporated from cognitive psychology and artificial intelligence. Alternatively, from an ecological perspective, we may consider the way in which the flexible behavior of plants gets structured as a result of the way internal and environmental factors couple together non-computationally. We can thus explore the guiding role that different models and theoretical frameworks may play.

### Predictive Processing

Anticipatory behavior could rely on estimating the likelihood that one particular state of affairs, and not another, is the source of energy.

According to the “predictive processing” hypothesis (Calvo and Friston 2017), plant perception boils down to a process whereby environmental input is matched to predictions generated endogenously by the system. It is the end result of a process whereby, first, top-down predictions of sensory signals – the conditional probabilities of particular features being the cause of stimulation – propagate backward to the effector organs and, then, predicted inputs are compared with incoming inputs: if predictions fail to match the input signals, the mismatch (a prediction error) is propagated upward. To accomplish it all, plants must embody a model of the causes of the inputs in question, a model whose predictions ensure that prediction error is minimized over time.

Plants may be seen as performing Bayesian model selection. Perception would consist in an active process of probabilistic inference with plants behaving like little statisticians that make tacit inferences about their world through changes in their internal states (Calvo et al. 2016). In order to pass predictions and prediction errors around the plant body and minimize prediction error, a hierarchical organization with reciprocally connected cell populations encoding expectations and prediction error is needed. In the case of plants, there is a functional asymmetry between backward predictive signals from deep vascular cell bundles and forward prediction error signals from mechanoreceptors and chemoreceptors located on the periphery of the plant body that could serve to implement predictive processing.

Prediction error may be minimized in two complementary ways: by updating expectations or by re-sampling. In the former case, a plant may adjust its internal states by updating its expectations so as to furnish better predictions (prediction error is minimized by updating expectations in order to bring them into line with actual states). Such process is called “perceptual inference.” In the latter case, a plant may choose to sample the environment more selectively in order to make new samples match prior expectations. This process is called “active inference.” Probably, prediction error minimization is accomplished through a

combination of both forms of inference. Overall, we may say that plants engage with their surroundings proactively, sampling the local environment in order to elicit information with an adaptive value.

### Ecological Psychology

Contrary to predictive processing, from an ecological point of view, environmental sources of stimulation are not ambiguous, and therefore perception need not be inferentially mediated to enrich an inherently poor landscape. Ecological perception relates to the detection of rich environmental information and is organized around actions. Plants resonate directly with informational invariants that specify opportunities for behavioral interaction whereby an unambiguous environment can be perceived directly (Carello et al. 2012). From the standpoint of ecological psychology, attention is paid to the ecological scale at which interaction takes place. The unit of analysis is the plant-environment system itself. This setting allows ecological psychologists to study plant adaptive behavior in terms of emergence and self-organization.

Consider a coupled system such as a climbing plant and its support or host. According to the ecological psychology framework, a vine would perceive its surroundings in terms of biologically relevant interactions, picking ecological information up as it circumnavigates around and explores its surroundings. Opportunities for interaction are then said to be perceived in the form of affordances, properties of objects that specify ways to interact with them, and guide the climbing maneuver in a continuous and cyclic loop of perception and action. The vine does not infer the support’s availability for twining; it rather perceives *climbability* itself, the possibility to interact with a support that affords climbing.

More generally, a foraging plant growing toward light or a source of nutrients behaves in functionally the same way as an animal that runs toward its prey. The hypothesis is that plants, like animals, resonate to specificational information without cognitive mediation of any sort whatsoever.

## Recent Developments

Many areas of research in plant signaling and behavior are receiving increasing attention in recent years, spanning from numerosity and swarm intelligence to the very possibility of visual guidance and plant sentience, among others.

### Numerosity

Sensitivity to numerosity does not require awareness or symbolic processing. The carnivorous plant *Dionaea muscipula* (Venus flytrap) exhibits numerosity-related abilities, being able to count to five (Böhm et al. 2016). More specifically, *Dionaea* is able to keep count of the number of times it fires action potentials in response to stimulation of the trigger hairs in the snap trap. Mechanical stimulation, such as the touching or bending of the trigger hairs, induces an all-or-nothing action potential. This, in orchestration with hormonal signaling, results in the closing of the trap. But for the snap trap to shut, a second stimulation must be repeated within 20 s of the first. If 20 s elapse with no news, short-term memory decays, and the plant forgets the first stimulation and resets – an adaptation that avoids unintended closure due to, say, raindrops or wind. The first stimulation must be somehow stored in the memory, if the plant is to eventually be able to put a further touch in a meaningful context. Once the trap has been shut, *Dionaea* keeps counting episodes of mechanical stimulation until it reaches five. This is important because after the initial two action potentials, three more are needed before digestive enzymes are synthesized and released.

### Swarm Intelligence

Members in flocks of birds, schools of fish, or swarms of insects responding to sensory input in the vicinity such as the pattern of navigation of the closest mate are the canonical illustration of swarm or collective behavior. But mechanisms that give rise to adaptive forms of collective behavior are widespread, with recent examples of collective behavior coming from the non-animal literature. *Escherichia coli* and *Salmonella typhimurium*, for instance, swarm and spread in

colonies. *Myxococcus xanthus* bacteria exhibit multiple forms of collective behavior. These rod-shaped myxobacteria glide their way through with a smooth continuous motion in swarms known as “wolf packs.” Plants are able to solve problems collectively too (Baluška et al. 2010). Maize roots, for instance, choose direction and rate of growth, reorienting selectively with respect to other roots in the vicinity to respect alignment (Ciszak et al. 2012). They can estimate distance, direction of nutrient gradients, and potential competition and adjust navigation patterns accordingly. By growing together and scanning the soil structure collectively, root systems are able to enhance the detection of nutrient patches.

### Visual Guidance

Recent evidence with the cyanobacterium *Synechocystis* suggests that directional light sensing is mediated by the use of primitive eyespots equipped with microlenses (Schuergers et al. 2016). We find likewise eukaryotic ocelloids in warnowiid dinoflagellates. These algae are equipped with a lens and a retina-like structure with pigments at the back that permit to tell the direction of light. The conjecture that plants have plant-specific eyes or ocelli first appeared in print at the beginning of the last century with Gottlieb Haberlandt's *Die Lichtsinnesorgane der Laubblätter*. As Haberlandt argued, leaf epidermis cells could play the role of sense organs functionally equivalent to animal ones. Commenting on Haberlandt's hypothesis, Francis Darwin subsequently elaborated on the idea that ocelli, in their simplest form, are nothing but an epidermis cell with a dome-like wall. As the cell is illuminated, sunrays effectively get bent, delivering a spot of light on the basal membrane. Plant mimicry in the woody vine *Boquila trifoliolata* provides the latest case for the study of plant vision. *B. trifoliolata* mimics the leaves of the host trees it climbs onto, copying not just the shape and color of host tree leaves but also their size, orientation, petiole length, and vein conspicuousness (Gianoli and Carrasco-Urra 2014).

Two hypotheses as to the mechanism that underlies mimicry are volatile organic compound-based airborne communication and

horizontal gene transfer, with parasites or microbes acting as vectors for gene transfer in between vine and host tree. Considering that mimicry takes place in the absence of touch, a further hypothesis has been advanced: *B. trifoliolata* may perceive their surroundings by forming primitive images courtesy of the visual sensory organs located in their leaves (Baluška and Mancuso 2016). This way, the vine could perceive shapes and colors courtesy of some kind of plant-specific vision akin to the ocelloid-based form of vision documented from research on cyanobacteria and some dinoflagellates. The internal structure of leaves, on top of furthering photosynthesis, could serve to bolster light sensitivity beyond mere photoreception. A transversal cut to a leaf reveals the candidate mechanism that can sustain vision. In particular, three main regions that bear vision-related properties have been identified: a cornea-like cuticle, convex or plano-convex lenslike epidermal cells promoting the convergence of light rays, and the retina-like mesophyll tissue.

### Sentience

The evolution of subjective experience has become a hot topic of research in recent years, with different attempts being made to trace subjectivity at various phylogenetic stages. Evolutionary biology has traditionally put the focus on the Cambrian period to understand the origins of sentience, more specifically, with the explosion of land vertebrate life. But animal sentience may also include invertebrates. The degree of sophistication of the perceptual apparatus of insects and their manifest capacity to learn, memorize, make decisions, and communicate appear to license the quest for the origins of mind beyond vertebrates or mammals in particular. If the mammalian mid-brain plays a key role in sensing and feeling, the central ganglion of insects plays an analogous role. But the origins of subjectivity could date back to the very origins of life itself, as the *cellular basis of consciousness* hypothesis sustains (Reber 2018). According to this hypothesis, the issue boils down to biomechanics, endogenous control, and navigation, and not to neural correlates. If the behavioral repertoire of insects hints at

their mentality, the same may hold for bacteria, whose wide range of competencies are only beginning to be fully appraised. Bacteria would have their own subjective experience, however basic the ascription of consciousness might be.

One way or another, consciousness may have evolved across evolutionary time a number of times. In recent years, the candidacy of plants for sentience has been given due consideration. If, despite the manifest lack of neural correlates of consciousness, bacteria evolved biomechanical structures that underlie their own subjective experiences, there is no reason to exclude the possibility that plants also evolved subjective experience. Plants lack none of the functional structures allegedly needed. Plant anticipatory behavior is goal-directed and soft-wired. Plants make decisions, solve complex problems, learn, memorize, and communicate. All this requires coordination and integration of information signaling across the whole plant body. Plants act as globally organized and coherent systems, supporting in principle their capacity for subjective experience (Calvo et al. 2017).

## Definition

Plathyrrhines or New World (Neotropical) monkeys live in South and Central Americas and are mostly arboreal (tree-dwelling) species. Primate communication occurs when one individual influences the behavior of another through the transmission of specific signals (e.g., vocal, chemical, tactile, and visual signals; Fig. 1). Natural selection of a given signal modality will basically depend on the habitat restrictions and social structure of the monkey species in question.

## Introduction

Whatever the definition of communication one adopts, an overriding aspect remains unchanged: the existence of a communication signal. A signal represents the form in which communication is performed and it can be expressed through vocalizations and nonvocal sounds (teeth chattering or trunk drumming, for example), color and facial expressions, postures, movements of the body or body parts, odors, touch, and even changes in the environment (e.g., shaking branches or clearing a path). Besides the signal, there are three other broad interrelated components that explain how communication works: motivation, meaning, and function (Scott-Phillips 2008). The motivation refers to the internal, emotional state of the animal performing the signal, such as, states of fear, aggression, alarm, excitement, and the social interest. Thus, the study of communication in animals may reveal ecological and behavioral aspects of a species. The meaning refers to the message that is received by the receivers of the signals. Recipients of different ages, experience, history, and relationship with the signaler may respond differently to the same signal at the same time. Finally, the function of a signal refers to the evolutionary advantage it confers to senders and/or receivers. In other words, function relates to the survival or reproductive advantages a signal gives to sender(s) and/or receivers. Alternatively, it is the answer to the question: what is the signal for? Thus, for example, when one says that the function of a bird song is to attract a female, such

**Platyrrhine Vocal Communication, Fig. 1** Communication modalities in Platyrrhine monkeys: Chemical, visual, tactile and acoustic. statement implies that attracting a female (and informing species identity and some characteristics of the sender) confers reproductive advantage to the sender.

Animals can use several ways to communicate and, depending on the type of signal employed, communication can be classified as: acoustic (sounds), visual (color or movement patterns), chemical (molecules diffusing in the medium), electrical (production of electric fields), and tactile (contact). Acoustic signals have several advantages over the other signals because of their wide transmission. It is generally possible to know where an acoustic signal comes from, without necessarily looking at or being near the sound source.

This entry will focus on acoustic communication, the modality most widely studied in New World Monkeys. For a better understanding of primate auditory communication, it is fundamental to consider sounds both from a behavioral and

a structural approach. Vocal communication studies can be roughly split into two broad groups: those describing the acoustic repertoire of a species and those dealing with some specific aspect of a given call. In the latter case, it is useful to group calls from different species according to their main function. Another way to group the studies is according to their contribution to a broader theoretical theme. In this entry, both approaches will be adopted, starting with repertoire studies, passing through studies with specific types of calls, and finishing with more theoretical themes.

### Nonacoustic Communication (Tactile–Visual–Olfactory)

Many Neotropical primates have been reported to communicate using olfactory, visual, and tactile cues. Olfactory signals can act as mediators of

intragroup and intergroup interactions. Scent marks through secretion of different glands are the commons marking modes used by most species. Adult males of titi monkeys, *Pleurocebus* and *Callicebus* genera, and common marmosets, *Callithrix jacchus*, for instance, spread some odoriferous secretion when they rub their chest along a branch (Moynihan 1966; Eppe 1970). Some other species, like muriquis (*Brachyteles hypoxanthus*), investigate the reproductive status of females by sniffing or tasting their genitals (Strier 1992). Individuals of both sex of capuchins and muriquis are also known to wash their hands with their urine (urine washing), and pheromones presented on it may convey information about sex, identity, and reproductive status (Milton 1985; Phillips et al. 2008).

Visual signals include facial expressions, postures, and movements of the body or some part of it (including interactions with the environment), and color patterns. For example, muriquis (*Brachyteles hypoxanthus*) have a greeting face, performed between adult males and females, which looks like a grimace, and is accompanied by specific vocalizations (Milton 1984). Many species show pilo-erection (body hair standing up) during agonistic contexts, and some, like titi monkeys (*Pleurocebus moloch*), show a large repertoire of other visual signals during such contexts, including but not limited to, swaying, arch-posture, tail-raising, tail-lashing, and head-down (Moynihan 1966).

Tactile signals have been much less studied than the other modalities. Clear-cut examples are restricted to some behaviors which might have communicative function. Among these, we have the embracement between adult muriquis, which is performed as a friendly gesture or during moment of excitement. Some researchers also consider the time animals spend in contact, while resting, for instance, as a tactile signal, especially because animals may choose who to be in contact with.

## Acoustic Communication

Acoustic communication is the modality which employs sounds as signals. Sound signals have

several advantages: they can be transmitted at a distance, in the absence of visual contact (thus in the dark, in water, or in dense vegetation), they go round obstacles, they show great capabilities of modulation, being thus able to encode a wide variety of information, and they travel fast in the environment. Accordingly, they are employed in a wide variety of situations to perform an equally large range of functions: play, mate attraction, territory demonstration or defense, mate defense, alarm against predators, travel coordination, group cohesion, mother–infant interactions, and several other affiliative and agonistic interactions. Therefore, the ability to produce and hear such an array of sounds is essential to many animals, and Neotropical primates are no exception. All Platyrrhine species employ acoustic communication for a variety of functions, and all species studied so far have been documented to have a relatively large repertoire.

## Acoustic Repertoire

Acoustic repertoire refers to the variety of sounds employed by a given species. Biological sounds can show an impressive range of variation on several different axis: frequency (from infrasound through bass, medium, and treble and up to ultrasounds), duration, frequency modulation (e.g., upsweep, downsweep, and flat, besides more complicated modulations), amplitude (loudness), rhythmic pattern, tone-like aspects (from “pure”, to harsh, hoarse sounds) to name just a few. Furthermore, sounds can be combined into sequences, adding further levels of complexity. Thus, describing the repertoire of a species is usually a basic, necessary first step on which more advanced studies can be built. However, categorizing sounds is not a trivial task, as there is no standard definition for an acoustic unit (see review in Kershenbaum et al. 2014), and defining the boundaries may be seen as arbitrary and subjective. Even with such difficulties, repertoire studies normally categorize the different sounds produced by a species, describe their physical properties, and usually mention the contexts and situations of emission, commonly proposing

hypothesis for their functions. However, despite their importance, we are still short of repertoire studies and, for most New World Monkey species, their repertoire is unknown or poorly studied, resulting in the function and meaning of many different calls remaining unknown.

Despite the differences in categorization, the size of vocal repertoire can also vary widely based on whether the study groups are wild or captive. This is also problematic as captive animals are often limited in their natural vocal repertoire due to the lack of some behavioral and social conditions. Furthermore, some studies usually focus on a particular context instead of a full description of a repertoire, and until very recently, many reports on the vocal repertoire of Platyrrhine species were based on only qualitative observations. The ideal scenario would, thus, be to study the same species both in the wild and in captivity in a variety of contexts to get a thorough representation of their whole acoustic repertoire.

Although there is considerable support for a fixed vocal repertoire for many primate species, other works have also shown some vocal plasticity, based on social interactions or human impact on the environment (e.g., Roy et al. 2011). These abilities are particularly important to help animals deal with some of the disadvantages of acoustic signals, as they may be degraded, or attenuated by factors such as temperature gradients, incidental noise, air currents, or even eavesdropping. For example, to deal with the last issue, woolly monkeys (*Lagothrix poeppigii*) are able to adapt their behavior and avoid calling in areas with high level of human hunters, which would give away their position (Papworth et al. 2013). There is also evidence of regional dialects in some calls of pigmy marmosets (*Cebuella pygmaea*) (De la Torre and Snowdon 2009).

Moreover, the type of calls in a given repertoire (e.g., discrete – calls being clearly distinguished from one another – or graded – calls grade more or less continuously into one another) can impact substantially on the number of calls identified by a given study. Therefore, it is important to consider an acoustic repertoire as a representation of combined distinct calls, variants, gradations, and transitions between them, besides keeping in

mind that is both an arbitrary, albeit useful, concept, and a working hypothesis. Acoustic variation on a call type can signal more information on the category of the external event, motivational or internal state. B-calls (“cheeps”) produced by titi monkeys during encounters with terrestrial predators, for instance, are also given when they are descending or feeding close to the ground. However, significant differences between the calls given in different contexts suggest they may be able to communicate about specific aspects of their environment, by changing some features of the same call.

To more fully understand the function of a sound, or a group of sounds, in different circumstances, we need two complimentary approaches. On one hand, we need detailed comparisons of the sounds in the different circumstances to check if there is significant acoustic variation. Then, either if the sounds are different or not, we need playback studies to see if the animals respond differently to them and/or if they extract meaning from the immediate context (and if the responses make sense in adaptive terms).

### Alarm Calls

Several mammal and bird species produce alarm calls that typically function to signal the presence of predators to conspecifics and/or communicate to the predator that it has been detected (Caro 2005). These call types may show variation in the structure of calls, the number and composition of calls given, and/or the intensity of calls depending on the context in which they are produced (e.g., Seyfarth et al. 1980). Such context-dependent calls can potentially evoke reactions in call receivers that are appropriate for the context in which the calls were given (e.g., Seyfarth et al. 1980). Among those species that produce context dependent alarm calls, two distinct types of call systems have been identified: (1) a “functionally referential” alarm call system, where call structure varies based on threat type (e.g., eagle versus leopard, Seyfarth et al. 1980) and (2) an “urgency-based” alarm call system, that varies based on the degree of threat from a predator perceived by a caller (e.g., high versus low; Blumstein 1999). Moreover, there are also alarm

call systems that combine both functionally referential and urgency-based systems simultaneously (Marler et al. 1992).

Researchers have reported alarm calls as an antipredator behavior for almost all primate species that have been studied in that respect. However, most reports from New World Monkeys come from anecdotal observations and little or no information on type and function of the calls is usually provided (see review in Cäsar and Zuberbühler 2012). In general, alarm calls given to dangerous raptors are usually more specific than alarm calls given to disturbances on the ground, which sometimes are also given during nonpredatory events. Wheeler (2010), for instance, described three different call types given by tufted capuchin, *Sapajus nigritus*, that were regularly produced in response to predator encounters. “Barks” were elicited exclusively by aerial threats, while “hiccups” were produced in response to terrestrial threats but also during nonpredatory contexts. The call rate of hiccups also reflects risk urgency and responses to playback of these calls elicited appropriated antipredator behaviors. A third call, the “peep,” seems to be specific to terrestrial threats (Wheeler 2010).

Some species also appear to be able to create, and understand, specific combination of a limited number of calls, which leads to a variable sum of distinct sequences that differ in distinct contexts. For example, cotton-top tamarins (*Saguinus oedipus*) produce some alarm and alert calls combining other call types, which are given in contexts described as intermediate between the contexts in which each call type is produced alone (Cleveland and Snowdon 1982). Digweed et al. (2005) have also suggested that capuchins’ (*Cebus capucinus*) alarm calls may recruit conspecifics to mob, a behavior well documented in other capuchin monkey species. Mobbing involves one or more prey animals making repeated and aggressive advances on a predator, usually while vocalizing and displaying in a conspicuous manner. These conspicuous and persistent approaches usually distract or repel the predator and are fairly common in New World monkeys. Capuchin monkeys (*Sapajus nigritus*) one of the most studied Neotropical primate genera regarding its vocal

behaviour also use alarm calls deceptively to diminish competition within group during feeding bouts (Wheeler 2009).

### Contact Calls

Animals that live in groups, whose members spread out during their daily activities and who live in habitats of poor visibility (such as in forests or water), need a mechanism to keep track of one another while spread apart and/or to re-gather and/or to coordinate their group movements. Among the communication modalities animals could use to accomplish those tasks, touch is not a possibility, since the animals are separated by definition (often by large distances), visual communication is precluded by the very nature of such habitats, and chemical communication is slow and its directionality is highly unpredictable. Thus, the acoustic mode is the one showing more advantages, and, in fact, this is the modality most widely used in such habitats to perform these contact functions. Accordingly, contact calls is the broad term that encompasses calls that group animals use to maintain contact with one another or regain contact after spreading out (see review in Cunha and Byrne 2009). In the literature, they have been diversely classified as isolation/lost calls, monitoring calls, cohesion calls, and contact calls (or its function is apparent in the description of context of use or the proposed function in repertoire studies). These kind of calls has been mentioned or described in virtually all primate species whose repertoire have been studied so far, and Platyrrhines are no exception. All Platyrrhine genera (apart from *Oreonax*, *Chiropotes*, and *Mico*, whose repertoire have not been studied, and for which only sparse information is available) have been shown to have at least one call of their repertoire which could be labeled as a contact call. Nonetheless, the studies with New World monkeys contact calls are usually restricted to such basic repertoire studies, with just a couple of exceptions dealing exclusively with them or using them to answer a broader theoretical issue (mostly studies looking for individuality in the calls). Nonetheless, as Cunha and Byrne (2009) argue, they have the potential to be used to test hypotheses about intentionality on call emission,

besides begging for more detailed studies, attempting to find these call-specific functions.

### Loud or Long-Distance Calls

Loud or long-distance calls, is a commonly used term in the bioacoustic literature. Although obviously subjective, it usually refers to those calls which are distinctly louder than the other sounds in a species repertoire and/or which seem to be directed to receivers outside the immediate group/sub-group or surroundings of the call emitter. Primate loud calls are typically interpreted as signals of intergroup communication, although they can also function as conspicuous antipredator alarm calls.

Several Neotropical primate species produce loud calls that function for announcing group location, spacing groups, defending mates, and advertising group composition. Howler monkeys (*Alouatta* spp.), for example, whose name comes from their conspicuous loud calls, produce long, loud, and harsh roars and barks, which are amplified by an enlarged hyoid bone present in males. Despite being one of the most studied genera in that respect, no agreement has been found for the calls' function, which have been diversely proposed to work in mutual group avoidance, announcement of group location, marking and defending territorial boundaries, and defending mates, to name some of them. Another well-known loud call is the duet, a long and loud sequence of calls which is uttered by the mated pair, and sometimes their offspring, in a coordinated way. This behavior is an important feature of titi monkey species, genera *Callicebus*, *Cheracebus*, and *Pleuturocebus*, and also seems to be part of a territorial behavior, to define and reinforce territorial boundaries.

### Food Calls

Many New World monkeys produce food-associated calls upon encountering or feeding of specific food items. These calls usually provide information about the type, quality, or quantity of

food, and it may be influenced by the audience. Spider monkeys (*Ateles geoffroyi*), for instance, call more in the presence of dominant animals, and in larger trees, with more availability of food, than in the presence of subordinates and in small trees (Chapman and Lefebvre 1990).

Food calls may function to attract conspecifics to a food source or to announce ownership. Although several Neotropical species have been reported to produced food/feeding associated calls, including *cuxius* and *uacaris*, the function of these calls is still to be tested (Bezerra et al. 2017). Food-associated calls in Neotropical primates have also been reported to happen during food transfer, through infant begging, or the calling of the food possessor to attract group members. Some Neotropical primate infants, especially marmosets, tamarins, and Goeldi's monkey are also known to beg for food, through specific body movements and vocalizations.

### Taxonomy

The use of acoustic signals occurs widely in Primate species, both intra and interspecifically, and such signals are known to vary in their physical structure. Primatologists often use such signals to help locating and surveying their primate species because of the acoustic diversity encountered in these animals. In fact, acoustic diversity has been used as one mean to solve taxonomic uncertainties (Blair et al. 2011). Moreover, loud or long distance calls can be used as a fingerprint to help differentiating among sibling species for taxonomic diagnosis (Hending et al. 2017). Quantitative knowledge of vocal repertoires can help in such tasks, through acting as the basis for comparative analysis (Fischer et al. 2016).

The differentiation between species based on acoustic properties of the calls has already been proved efficient for *Callithrix* species in the Neotropics (e.g., Snowdon et al. 1986). Calls from different primates do sound and look spectrographically different (Fig. 2). Currently, we only know of the vocal repertoire of about 10% of the

**Platyrrhine Vocal Communication, Fig. 2** Structure of vocalizations from four South American monkeys, showing their differences. (a) *Sapajus flavius*, blonde capuchin monkeys (Image: Bezerra – camera trapping);

(b) *Callithrix jacchus*, common marmosets (Image: Bezerra); (c) *Saimiri sciureus*, squirrel monkeys (Image: Campelo); (d) *Callicebus nigrifrons*, black-fronted titi monkeys (Image: Cäsar)

Platyrrhine primates (e.g., Bezerra et al. 2017). As a result, basic research to fully describe the vocal repertoires of Neotropical primates is urged, so that vocalizations can be used as a behavioral character to supplement other taxonomic data to study primate phylogeny and provide taxonomic elucidations.

## Referentiality

Primates communicate about objects and events in their environment in ways that allow recipients to draw inferences about the nature of event experienced by the signaler. This finding has relevance to theory addressing the origins of human language, a system strongly characterized by referential communication (e.g., Fitch 2010). Previous research efforts, however, have been heavily biased toward Old World primates with relatively few studies with New World monkeys, providing limited scope for the development of theories addressing the evolutionary origins of language-relevant capacities. Functionally referential calls must show both context specificity of call production, where the signal is produced in a context-specific way, and perception specificity, where the signal alone is sufficient to evoke an appropriate response to listeners in the absence of the eliciting stimulus (Macedonia and Evans 1993). When studying two sympatric species of tamarins (*Saguinus fuscicollis* and *Saguinus mystax*), Kirchhof and Hammerschmidt (2006) have found that these animals responded with adequate antipredator reaction after hearing playbacks of calls originally given to aerial and terrestrial disturbances. In another study, Wheeler (2010) provided evidence that tufted capuchin monkeys (*Sapajus apella*) also showed appropriate responses after hearing “barks” (aerial predator calls) and “hiccups” (generalized disturbance call), which were produced in the relevant contexts. Recent studies have also shown that black-fronted titi monkeys (*Callicebus nigrifrons*) produce vocalizations in response to natural and experimental predator models. Habituated

groups reliably uttered one of two alarm call types, call A (“chirps”), as a first response to raptors (whether flying, perched or calling) in the canopy and the other alarm call type, call B (“cheeps”), in response to several disturbances on the ground, including to species of predator models (snakes, oncilla, puma, and tayra) and to a control stimulus (deer) on the ground (Cäsar and Zuberbühler 2012). Further evidence suggested that some of these sequences are meaningful to conspecific receivers, by indicating the general predator class and location of threat (Cäsar et al. 2012). Analyses of call order and number of calls per sequence suggested that callers might be able to convey information about predator type and location (Cäsar et al. 2013). However, playback experiments are still needed to investigate if listeners are able to attend to these sequential variants. Although relevant, this selection of studies almost comprises the entirety of researches on referential communication with Neotropical primates alarm calls. The situation is in striking contrast with the research agenda on Old World monkeys and apes, thus begging for an urgent broadening of the research with Platyrrhines. Also, up until now, there are only a few studies with reference calling in feeding, and none in social contexts, which creates a huge gap in our knowledge of referential communication in Neotropical primates.

## Applied approaches

Besides their intrinsic interest, researchers have recently started to use primate calls to pursue more applied objectives outside the behavioral domain, particularly so in surveys and censuses. The first, and most basic, way to do so is to include vocalization as indirect evidence of the presence of a species. With some training, researchers can estimate distance of the caller(s) to their location. Then, alongside data on the direction of the call (with a compass), researchers can then use calls in more systematic surveys, as suggested by Gestich et al. (2017). Whichever the approach, researchers

can further improve study design by playing back calls in their study region through a loudspeaker (usually loud calls, particularly if employed in intergroup agonistic interactions). Such broadcasting is carried out in an attempt to stimulate individuals/groups to counter-call, thus increasing the chance of locating callers. Last, researchers have recently started to employ automatic acoustic recorders, which are devices deployed in the environment which record sounds at a previously determined schedule, being capable to operate for months in a row. Later on, the recordings are scanned (manually or automatically) searching for the sounds of the species of interest.

Future studies should also investigate the vocal behavior of other species, including species that are difficult to study in their natural environments, such as uacaris, cuxius, sakis, and night monkeys. A further way to improve knowledge on those species is to study them in captivity (Bezerra et al. 2017).

## Conclusion

Platyrrhines or New World Monkeys live in Central and South America and are mostly arboreal species. Communication occurs when one individual influences the behavior of another through the transmission of specific signals. Communication in primates can occur through vocal, chemical, tactile, and visual signals. Although many Neotropical primates have been reported to communicate using olfactory, visual, and tactile cues, acoustic communication is the most widely studied modality in this group. All Neotropical primate species employ acoustic communication for a variety of functions – including mate attraction, territory and mate defense, travel coordination, alarm against predators, and several affiliative and agonistic interactions – and all species studied so far have a quiet large repertoire. Although some genera or species have been studied significantly more than others, there is still uncertainty regarding the vocal behavior of even some of the most studied

animals. A major problem with some studies is that little effort was made toward precise quantification of call structures. Despite that, some recent studies have shown the presence of quite complex vocal systems, which have added some important information on the communicative abilities of New World monkeys; an independent radiation within the primate lineage with essential differences in life-history and socio-ecological characteristics from other primates.

## Definition

*Platyrrhine cognition* (from Latin *cognitio* which means “knowledge”) can be defined as the set of mental functions by means of which New World monkeys acquire and use information – knowledge – to solve the problems they face in their environment.

## Introduction

Platyrrhines, or New World monkeys (NWM), started their independent evolution from catarrhines, or Old World monkeys (OWM), about 30–40 million years ago, when they arrived to the then island continent of South America. Living species include nonhuman primates from South and Central America. They are a very diverse group of small to medium-size species (range, <100 g to ~10 kg in weight) characterized by distinctive ecological and morphological adaptations (Fleagle 2013). First serendipitous observations on platyrrhine cognitive capacities date back some centuries. The most famous one is probably that reported by the British naturalist Erasmus Darwin, the grandfather of Charles Darwin, who observed a capuchin monkey cracking open a nut with a stone in a park in London. Scientists like Erasmus Darwin, George Romanes, Thomas Belt, and Heinrich Klüver were impressed by the abilities of capuchin monkeys, although early prejudices against the intelligence of NWM in comparison to OWM and apes prevented their observations from being highlighted within the scientific community. Systematic research on platyrrhine cognition expanded in the second half of the twentieth century. Since then, the combined efforts of natural observations and controlled laboratory tests have

STUDIES ON PLATYRRHINES PUBLISHED IN *ANIMAL COGNITION* (1998-JUNE 2017)

**Platyrrhine Cognition, Fig. 1** Number of studies on platyrrhine cognition published from 1998 to June 2017 in *Animal Cognition*, an interdisciplinary journal publishing research on all aspects of animal cognition. Search performed on June 21, 2017 using both scientific and

common names of platyrrhine genera in article titles. Although far from being exhaustive, this search is supposed to reflect the relative amount of studies on different taxa published in the overall literature

produced much evidence of cognitive abilities by means of which platyrrhines solve problems both in physical and social contexts. The remainder of this entry touches several research areas on platyrrhine cognition. To date, a limited number of genera have been investigated, typically those widespread in cognitive laboratories, whereas many taxa have been less – or not at all – studied (Fig. 1).

## Platyrrhine Cognition in Physical Contexts

Platyrrhines live in forest environments. They have arboreal habits with little or any propensity to forage or move on the ground, except for some species of *Sapajus*, which can spend a large amount of time feeding on the ground (Fleagle 2013). There are only two genera, *Alouatta* and *Brachyteles*, that specialize on eating leaves, whereas most of the species specialize on fruits, tree gums, or insects. Mastering challenges in the physical environment requires the capacity to

locate and process food resources, avoid predators, and choose safe resting sites. Ultimately, this means to learn how to use information about places, foods, and dangers. To deal with such problems, each species is equipped with its own peculiar anatomical and mental characteristics to perceive, memorize, and categorize external information and to plan and perform appropriate actions.

## Perceiving Objects

Perception allows the integration of information coming from sensory systems into organized stimuli (objects, sounds, tastes, etc.). Primates mainly rely on sight to gather information from the environment; therefore, the way they see the world deeply affects their cognitive abilities. Visual stimuli are identified by means of several perceptual cues such as color and shape. Excellent color vision is a prominent characteristic of primates in comparison with other mammals; therefore, it is one of the best-studied aspects of vision in these species (Jacobs 2012). Color perception is essential for primates to distinguish ripe from

unripe fruit, to identify ripe fruit and young red leaves against a background of green foliage, and to detect the coloration patterns of both preys and predators. All platyrrhines are active during the day and capable of perceiving colors, apart from the nocturnal genus *Aotus*. In most diurnal platyrrhines, heterozygous females have three color receptors (trichromatism), whereas homozygous females and males have two color receptors (dichromatism) and cannot easily distinguish reds and greens, as color-blind humans. In addition to colors, animals use other perceptual cues to group single parts of the perceived field to form an object. A fundamental property of visual scenes is that they are organized hierarchically: scenes are made up of different objects, which themselves are organized into parts and elements. There is evidence of perceptual grouping differences across primate species. Since the pioneering work by David Navon (1977), it has been repeatedly demonstrated that human vision starts from an analysis of the global configuration of the scene and only subsequently proceeds to the analysis of the details. Among platyrrhines, preference for global or local information has been studied extensively in captive capuchins. Capuchins show a mode of processing opposite to the global dominance of humans, despite the similarity of their visual systems. When tested with a variety of tasks presenting figures made of smaller elements that form larger configurations, capuchins detect more accurately local elements than global configuration of visual stimuli. A similar tendency to privilege the local elements has also been found in catarrhines of the genus *Papio* and in birds (Aust 2017; Fagot et al. 2012). It is still unclear whether and to what extent perceptual grouping processes affect object identification strategies of different species.

### Memorizing Objects and Places

Learning and memory allow animals to acquire information at one time and to retrieve them at a later time. Thanks to these abilities, past experiences can be used to adopt more efficient behaviors in the future. Monkeys need to learn and memorize information important for their survival, such as what types of food or objects are

located at particular sites in their territory. For efficiency of movement between feeding sites, animals must be able to memorize topographical features and reference points that are fixed in their location (landmarks) and therefore are reliable indicators of places. They can use cues such as landscape contours, forest margins, and trees of particular shape or size to move from one location to another. Several studies found that NWM as marmosets, squirrel monkeys, tamarins, and capuchins can memorize a landmark and use it as a beacon to find hidden food. However, among these taxa, only tamarins seem to be able to locate hidden food using the spatial relationship between multiple landmarks, which means they can rely on a configuration of multiple landmarks as a single source of information (Dolins and Mitchell 2010). It is still controversial precisely how NWM integrate spatial information and if they use internal representations of the space (*cognitive-like maps*) to reduce travel time and effort.

Along with the ability to memorize places, animals need to bear in mind objects through space and time even when they are currently not perceived. This ability, called “object permanence” (Piaget 1952), develops very early in human ontogeny and is widespread in the animal kingdom (Cacchione and Rakoczy 2017). According to Piaget, cognitive development in infancy proceeds in stages that correspond to different levels of representational abilities, and his theory has proved as a useful framework for developmental and comparative studies. Findings on NWM tested so far (tamarins, marmosets, capuchins, woolly monkeys, spider monkeys, squirrel monkeys) showed that most species can keep track of and search for objects displaced in full view of the subject (*visible displacement*), whereas their ability to track the displacement of hidden objects (*invisible displacement*) is more unclear (Cacchione and Rakoczy 2017). For example, in the *transposition task*, in which the object is placed under one of two/three containers, while the subject is watching and the containers are subsequently shuffled without revealing their content, capuchin and spider monkeys located the baited container significantly less than great apes. So far, only few individuals of marmosets,

tamarins, capuchins, and spider monkeys solved the invisible displacement tests suggesting that the cognitive load imposed by these tasks verges on the upper limit of their representational abilities. Mastering such problems involves the mental reconstruction of an unseen trajectory, rudimentary logical reasoning, as well as the ability to refrain from searching in previously rewarded locations and to retain relevant information for a varying amount of time.

### Motor Planning for Reaching and Grasping Objects

Motor actions, such as reaching for and grasping objects, are often guided by the actor's *anticipation* of upcoming postural and task demands. This ability may provide a scaffold for the development of more sophisticated cognitive abilities such as tool use, long-term planning, and inhibition. For example, in *detour* tasks, individuals have to refrain from reaching directly for a reward they can see, because it is blocked by a clear barrier, but they can access the food by going through a lateral opening. Capuchin and spider monkeys successfully inhibited the tendency to reach directly for food outperforming tamarins, marmosets, and squirrel monkeys (e.g., Rosati 2017). Interestingly, tamarins' performance at detouring improves when the barrier is opaque and food is not visible, probably because it is easier to control the prepotent reach toward food. Other experiments with NWM suggest that the rudimentary motor planning abilities appear to be shared across species (Rosenbaum 2017). Cotton-top tamarins presented with an upside-down transparent cup that had food stuck to its bottom interior grasped the stem of the cup with an uncomfortable hand posture (with the thumb down) in order to easily rotate it and reach a comfortable final hand posture. Recent evidence also suggests that squirrel and capuchin monkeys engage in similar motor planning. Moreover, capuchins show action-selection planning when using tools to interact with distally located targets. These findings suggest that NWM are capable of predicting the likely consequences of future movements and use that information to select proper actions.

### Using Objects as "Tools"

Once having grasped an object, primates can explore and manipulate it, for example, by combining it with another object or a surface. By performing object manipulations and combinations, they acquire information about objects, and the feedback generated from their actions can lead to the acquisition of tool use. Tools – as extensions of the body – allow obtaining goals otherwise difficult or impossible to achieve, for example, giving access to out-of-reach foods. Among NWM, capuchins are the only taxon in which "true" tool use is widely present. True tool use implies that the manipulator is responsible for the proper and effective orientation of the tool and uses it "to alter more efficiently the form, position, or condition of another object, another organism, or the user itself" (Shumaker et al. 2011, p. 5). Advanced perceptuomotor abilities are fundamental to develop manipulations that require the management of at least one allocentric spatial relation, that is, a relationship between the "tool" and a surface or another object (Visalberghi and Fragaszy 2012). Capuchins select and use tools on the basis of functional features and flexibly adapt to the requirements of the task at hand (Visalberghi et al. 2017). For example, they select stones, best suited to crack nuts open, on the basis of weight and/or the sound produced when tapped and not simply on the basis of size. Nut cracking is considered the most relationally complex form of tool use by nonhuman primates routinely found in nature and involves two allocentric spatial relations, one between the nut and the anvil and a second between the stone hammer and the nut. Capuchins typically manage these relations sequentially: the nut is placed and released on the anvil prior to striking it with the stone (Visalberghi and Fragaszy 2012) (Fig. 2).

To study also what other non-tool-using primate species understand about the functional characteristics of tools, researchers use tasks in which the manipulator is not responsible for the position of the "tool" and of other elements of the task (i.e., food and substrate or another object). In these experiments, monkeys are presented with two alternatives prearranged by the experimenter, and they have to pull one of two available "tools"

**Platyrrhine Cognition, Fig. 2** A male capuchin (*Sapajus libidinosus*) uses a stone to crack open a palm nut in Brazil (Photo: N. Spagnoletti)

(e.g., canes, hoes, sticks, strings, clothes) in order to obtain a food reward. In such tasks, cotton-top tamarins recognize that effective pulling tools must be made of rigid materials, but they do not recognize either the relationship between the tool's orientation and the position of the food reward or the relationship between the tool's trajectory and the substrate where it moves on (Ruiz and Santos 2013). Unlike tamarins, capuchins solve this kind of problems involving two and three relations (i.e., food, tool, and one type of hindrance – an obstacle or a trap – which could prevent success). For example, capuchins spontaneously use sticks to retrieve food placed inside a transparent tube. However, they do not seem to understand the relationship between pushing food with the tool and the substrate on which food travels (Visalberghi and Frigaszy 2012). In fact, when they had to push the food outside of the tube avoiding a trap, the only successful subject solved the task using the rule of “inserting the stick into the opening of the tube farthest from the reward.” These tasks are also used to investigate whether

primates understand that the tool must be in contact and connected with the reward in order to be functional. NWM tested (common marmosets, cotton-top tamarins, capuchins) could choose the tool functionally connected to the food after some training. Moreover, when presented with parallel and crossed-string configurations, some NWM seemed to use the strategy of choosing the string closest to the food (Seed and Mayer 2017). However, reliance on proximity is ineffective in other conditions, for example, when one of the strings is broken. In this case, participants have to choose between an intact and a broken string as means to a reward. Capuchins perform better in this standard condition than when nonfunctional perceptual cues are added (i.e., the original strings are covered by ineffective broken and unbroken strings), suggesting that they understand the task's functional properties.

### Quantifying Objects

The ability to deal with quantitative aspects of the world is adaptive in a variety of ecological contexts. During foraging, for example, it allows to evaluate if one fruit is larger than another fruit (nonnumerical quantification of continuous quantities) or if one tree has more fruit than another tree (numerical quantification of discrete quantities). Since the beginning of the twentieth century, research on animal cognition has given special attention to numerical competence because of its potential to shed light on how advanced human numerical cognition and mathematic reasoning emerged through evolution. Studies on discrete quantity judgments demonstrated that marmosets, tamarins, squirrel monkeys, and capuchins are able to discriminate food sets differing in numerosness. The vast majority of these studies have been conducted using two sets including a different number of food items. Similarly to other primates, platyrrhines are able to discriminate food sets differing in numerosness and to choose the larger food amount, although their discrimination ability is mediated by the ratio between the two quantities (Beran 2017). Discrimination becomes more difficult when the to-be-compared sets are more similar in quantity, and this difference approaches a 1:1 ratio. Such a *distance effect*

follows Weber's law, according to which the discriminability of two magnitudes does not depend on their absolute magnitude differences but on their ratio, and has been reported also in catarrhines (including humans) as well as in several nonprimate species. Moreover, some studies indicated that, similarly to other animal species, NWM are better with small than with large item sets, an effect called *size* (or *magnitude*) *effect*. Many authors explain the well-established *distance* and *size effects* with a core processing system, the approximate number system (ANS), in which quantities are represented inexactly, with increasing variance in discriminating or estimating set sizes as the true set sizes increase. The existence of a second system for quantitative judgments in nonhuman primates is still under debate, which is supposed to be a precise but size-limited system that accurately represents small quantities but cannot accommodate sets greater than four items because of limits in memory and attention.

### Understanding Similarities

If an appropriate response is known for a familiar object (or problem), it is important to use the same response also with novel objects (or problems) that resemble it. The ability to recognize similarities between objects enables an individual to sort stimuli into equivalence classes and to respond efficiently to novel objects saving cognitive resources. NWM, as other animals, can solve several cognitive problems based on physical similarity between objects. At the simplest level, monkeys can learn to choose objects featured by a certain characteristic such as color or shape when systematically rewarded to do it. Moreover, studies on capuchins found that they can solve more advanced matching-to-sample (MTS) tasks following similarity rules. In the MTS, individuals have to choose which of the two comparison stimuli resembles most closely a target stimulus (sample). Capuchins can solve the MTS with trained stimuli and, after extensive training, can also match stimuli they have never seen before. Dealing repeatedly with problems requiring similar solutions is proven to enhance generalization abilities; such an effect

has been found in many animal species including marmosets, capuchins, spider, and squirrel monkeys. Therefore, NWM are able to use not only similarities among objects but also similarities across sets of problems. According to Harlow (1949), this learning-to-learn pattern (*learning sets*) is a cognitive process indicating that an animal does more than adapt by trial and error to changes in the environment: it learns how to efficiently deal with similar problems it encounters over and over again. In general, the ability to understand and use similarities among objects and among problems emerges clearly in platyrrhines when objects or problems can be judged as similar on the basis of their physical features. On the contrary, in these species, there is still scarce evidence of the ability to manage similarities based on abstract relations which are weakly or, not at all, embedded in the perceptual domain (Thompson and Oden 2000; Wasserman et al. 2017).

### Platyrrhine Cognition in Social Contexts

Platyrrhines show an impressive range of variation in social systems, particularly in view of the comparatively narrow ecological range available to them (Fleagle 2013). Many of them live in monogamous social groups (*Aotus*, *Callicebus*, and *Pithecia*) that are seemingly stable for several years. One genus (*Alouatta*) lives in single-male groups in some environments and in multi-male groups in others or when the population density changes at different sites. *Cebus*, *Sapajus*, and *Saimiri* live in more complex hierarchical multi-male and multi-female groups. *Ateles*, by contrast, typically live in "fission-fusion" societies, in which the individual members of a large community associate on a daily basis in small and flexible parties, frequently changing size and membership. The relatively small marmosets and tamarins (Callitrichinae) show highly flexible patterns of social organization and mating system. These latter species are all communal breeders with many group members aiding in the raising of infants. Such platyrrhine diversity in social systems can thus be highly valuable for better understanding

**Platyrrhine Cognition, Fig. 3** (A) Howler monkeys (genus *Alouatta*), photo: I. Agostini; (B) squirrel monkeys (genus *Saimiri*), photo: A. De Marco; (C) common marmosets (genus *Callithrix*), photo: A. De Marco

the ecological causalities underlying primate social behavior and cognition (Fig. 3).

NWM thus need substantial cognitive skills to deal with intricate relationships and complex

social interactions. Individuals must recognize other group members and continuously track their position, social behavior, and foraging success; classify group members by attributes such as age, sex, and dominance rank; and update this information as circumstances change (Smuts et al. 2008). Even in callitrichines, which live in small groups, there are complex breeding systems that require enhanced socio-cognitive and communicative skills: individuals need to carefully monitor others, to reciprocally coordinate actions spatially and temporally, and to show high levels of responsiveness to others' cues. It is therefore not surprising that social context has been recognized as one of the main driving forces shaping the evolution of problem-solving capacity in primates (Whiten et al. 2011). The following sections will offer an overview of several cognitive skills that allow platyrrhines to successfully deal with their social environment.

### Learning from (with) Others

For many animal species, including NWM, the most pressing problems arise in locating and obtaining food. By living in groups, they can benefit from an increased opportunity for observing the foraging behavior of others and possibly learn about new types of food or new foraging techniques through social facilitation (King 1994). Social facilitation occurs when naïve individuals can learn to eat novel food more readily with others than when alone. For example, infants of both golden lion tamarins and common marmosets are more likely to eat novel food in the presence of adults eating the same food than when alone. Social facilitation occurs in capuchins too but seems to be aspecific: seeing companions eating motivates capuchins to accept novel food items, even when such food does not match with what others are eating. The opportunity to observe a skilled conspecific executing food manipulations can attract the attention of naïve individuals to some salient features in the environment (e.g., tools used to access food, food leftovers, place of food activities) and increase the likelihood of acquiring the observed behavior by individual learning. Such mechanisms, called “local enhancement” or “stimulus enhancement”

(Thorpe 1956), play a fundamental role in the acquisition of foraging techniques in many primates, including NWM. For example, common marmosets that could scrounge the leftovers produced by a model solving an instrumental task learned significantly better to obtain food compared to individuals that could only observe the model or with no social experience. Fragasz et al. (2004) have carried out the most systematic program of research on social learning on capuchins, observing them in several tool-use tasks both in the wild and in captivity. Their findings support the view that stimulus enhancement together with trial-and-error learning (i.e., individual learning) is at the basis of tool-use acquisition in these monkeys.

Evidence of more advanced forms of social learning in NWM are still very scarce (Tomonaga et al. 2012). One of the most debated learning processes is imitation, defined as the ability to learn by copying a novel or improbable behavior performed by others. Imitation is considered highly complex in cognitive terms because it supposedly relies on the capacity to attribute mental states to others (e.g., understanding other's goals or intentions). In general, it is knowingly difficult to experimentally rule out the effect of simpler forms of social learning when testing for imitation. To date, the only evidence of such ability in platyrrhines was found in common marmosets. Marmosets were tested with the *two-action method*: in such task, naïve subjects can watch two demonstrators that use different actions to solve the same task (e.g., opening a box by pushing a door or by sliding it laterally). Some subjects were able to accurately copy the action performed by the demonstrators, suggesting the occurrence of imitation. Such surprising performance is supposedly grounded in the cognitive mechanisms supporting the cooperative breeding systems of callitrichines.

### Understanding What Others Can (or Cannot) See

Often treated as the main cognitive gap between humans and other animals, the ability to

understand what other individuals “see” or “think” has been subject to immense research activity since Premack and Woodruff (1978) first asked: “Does the chimpanzee have a theory of mind?” Despite the effort, evidence for such skills in nonhuman primates (beside great apes) is still controversial and especially fragmentary in NWM. The ability to follow the gaze of others is an adaptive skill that might have been selected as a mean to obtain information about food location, predators, and social interactions among group members. From a cognitive perspective, a low-level explanation considers it an innate response triggered by something shifting individual's attention (like a human's head turn) to an external target, while higher-level explanations rely on the ability to understand what others see up to the more advanced capacity to form a mental representation of the visual knowledge of others. Many paradigms have been used to investigate perspective-taking abilities of NWM. Object-choice tasks, where subjects can use a (human) cue to infer the correct choice of a reward hidden in one of a number of containers, evidenced eye-following skills in marmosets and tamarins. The ability to follow other communicative cues was also found in squirrel and capuchin monkeys. A more difficult task requires subjects to track a looker's gaze that points toward objects hidden behind opaque barriers. In such situations, to identify the interesting object, the individual following the gaze of the looker needs to understand that in order to see what the looker can see, he needs to turn around the barrier. Both spider and capuchin monkeys succeeded in the task, while marmosets did not (Kaminski 2017).

Hare and colleagues (2000) studied perspective taking using a more ecologically valid approach, in which subjects are tested with conspecifics (rather than a human experimenter) and in a competitive context (rather than a cooperative one). This paradigm tests whether a subordinate subject would more likely go for a food item that a dominant individual cannot see than toward one that is in dominant's line of sight.

Such behavior would indicate that subordinate can take the perspective of the dominant subject. When subordinate capuchins were allowed to choose which piece of food to retrieve before the dominant would do so, they did not choose preferentially the hidden food, suggesting that they were not taking into account what the dominant could or could not see. By contrast, subordinate common marmosets showed a preference for the hidden piece of food, but such findings can be possibly explained by simpler cognitive mechanisms than true perspective taking, such as by perceiving conspecific's communicative cues as indicating a possessive relationship between looker and target object. The present state of evidence parsimoniously suggests that NWM do not have a true understanding of others' perspective and that simpler cognitive mechanisms could explain the abilities to exploit others' communicative cues.

### Working Together

Coordination allows the expression of fundamental shared activities in primates' life such as caregiving, vigilance, and group and territory defense. The cognitive functions underlying the ability to coordinate own's action with others stay at the core of social cognition: in coordination actions, individuals have to negotiate a shared goal, monitor the behaviors and the signals of partners, and somehow communicate their respective roles. High degree of tolerance may increase the possibility for individuals to act together, which in turn may set up the conditions for the development of more advanced cognitive skills of shared intentionality and for cooperating in ever more complex ways. Researchers have employed a large variety of methods and of paradigms in the effort to understand how, when, and why primates cooperate. In one of the most common experimental paradigms used in laboratory, two animals need to work together on a task to obtain rewards. For example, animals are required to simultaneously pull two ropes so to successfully reach a platform containing food or

to pull two handles to release some food reward. Although the protocols vary considerably, the logic behind is that if either one does not participate, neither will profit. Variants of this paradigm have been extensively applied to many species, including NWM: common marmosets, cotton-top tamarins, and capuchins all show the ability to coordinate their behaviors to solve the task, with tamarins being the species with higher efficiency rates (Cronin 2017). The success in reward achievement depends of course on many factors, firstly on how (or if) the reward can be shared among partners. Differences in the degree of tolerance across NWM species may play a role in determining the success in such joint tasks. For example, when partners are presented with a single reward to share, highly tolerant species such as cotton-top tamarins cooperate (albeit less than when both partners are rewarded separately), and in both tamarins and marmosets, cooperation is sustained even when the reward is given to only one partner. By contrast, cooperation is drastically reduced in less-tolerant species such as capuchins. The achievement of the reward may well depend upon the social relationship between partners. For example, in capuchins, cooperation levels (and reward sharing) are higher between close kin (e.g., mother-daughter) than non-kin. In a modified version of the string-pulling task in which only one partner is allowed to pull the rope and the other to grasp the food, marmosets cooperated, and the successful dyads were the ones in which the partner obtaining the food did not monopolize it.

Variation in task performance is used to evaluate what monkeys understand about this task and what cognitive abilities are used to solve it. For example, if subjects understand the cooperation task, they should rarely work when alone compared to when a partner is present. Indeed, capuchins are more likely to pull when their partners are present and in reach of the handle, but do not appear to time their pulls with those of their partners. Therefore, capuchins learn to make an association between the task and the location of their partners, although not considering the pulling as a

critical element of the task. Similarly, tamarins are more likely to manipulate levers in the presence of their partners than when alone suggesting some understanding of the role of the partner (Cronin 2017). The opportunity to monitor each other's behavior during the task is important too. It has been shown that if an opaque barrier is placed between the partners, capuchins can't sufficiently coordinate their pulling to reach the food. This suggests that coordination does not simply occur by chance but that some form of intentional cooperation is likely to occur. To sum up, these findings suggest that NWM are able to coordinate their actions in space and time and adjust their own effort in association with the presence, location, and relationship with their partners. The behavioral repertoire associated with the cooperative breeding system of callitrichines may help explaining why cooperation is more common and possibly more efficient in marmosets and tamarins than in species with less egalitarian social systems such as capuchins.

## Conclusions

Cognitive abilities evolved, thanks to the interplay of physical and social environmental forces. The study of platyrrhine cognition is crucial to disclose specific (sometimes unique) adaptations that each species has for its own physical and social environment. Some taxa are highly proficient in combining objects, as exemplified by the case of tool use in capuchin monkeys, whereas other taxa, like marmosets, stand out for their ability to imitate conspecifics. To date, cognitive capacities of the vast majority of NWM still remain poorly, or completely, unknown. Hopefully, future research will provide findings to fill this gap. Contemporary research can exploit increasingly advanced instruments to study animal behavior and cognition. The sad paradox is that most platyrrhines are increasingly endangered by the loss of their habitats and might not survive long enough to be studied.

<sup>2</sup>Department of Anthropology, Northwestern University, Evanston, IL, USA

### Introduction

New World monkeys belong to the primate infra-order Platyrrhini, and they include ca. 152 species (Rylands et al. 2012), 20 genera, 7 subfamilies, and 3 families (Cebidae, Atelidae, and Pitheciidae) (Groves 2017), distributed from southern Mexico to northern Argentina. They range in size from 100 g (pygmy marmosets) to 10 kg (muriquis), and despite being mainly arboreal, they occupy a wide variety of habitats and foraging niches. Fruit is an important component of the diet of most genera; however, they also include leaves, flowers, seeds, nuts, nectar, and invertebrate and vertebrate prey as foods. In addition, some genera show extreme specialization and anatomical and physiological adaptations for feeding on gums (*Cebuella*, *Callithrix*) and fungi (*Callimico*).

Traditional studies of primate feeding ecology describe the diet of different taxa according to the time spent foraging and feeding on different items. Recent frameworks in nutritional ecology recommend collecting and reporting feeding data based on the estimated amount of food and nutrients consumed by the study individuals (Garber et al. 2015), since the quantity of food actually ingested varies greatly depending on food characteristics, food availability, and age/sex of the forager. Obtaining more precise dietary data can be achieved by recording feeding rates (e.g., number of items ingested per minute) and collecting food samples, that later can be dried, weighed, and analyzed for different macronutrients (e.g., protein, lipids, carbohydrates), micronutrients (e.g., minerals), and secondary metabolites (e.g., tannins, alkaloids). Analyzing the nutritional

composition of the selected food items is particularly valuable due to the high variability in the nutritional content of plant parts belonging to different plant genera, species, and even individual trees. As a consequence, it is important to point out that broad characterizations and classifications of feeding strategies, such as folivory, frugivory, and insectivory, are not the best indicators of the nutritional and energetic quality of a diet.

An excellent example of this phenomenon is that primate communities in the Neotropics include more frugivorous taxa than those found in Asia and Africa. This pattern has been attributed to differences in plant species diversity and fruiting patterns as well as nutritional content on the American continent. Specifically, in the Neotropics, young leaves (a good source of protein) tend to be scarce during periods of low fruit availability; there is a high diversity of trees, such as figs, that can be “keystone” resources (i.e., resources that play a critical role in maintaining the structure of an ecological community) during times of general food scarcity; and fruits tend to contain on average more protein than fruits found at other sites (e.g., Madagascar) (Ganzhorn et al. 2009).

Nevertheless, platyrrhines display a wide range of dietary strategies associated with morphological, physiological, and behavioral adaptations. These strategies are generally shared by members of the same subfamily:

### Family Cebidae

#### Subfamily Cebinae (Genera *Cebus*, *Sapajus*, *Saimiri*)

Capuchins (*Cebus* spp. and *Sapajus* spp.) and squirrel monkeys (*Saimiri* spp.) are the two most omnivorous platyrrhines, since their diet can be composed of fruits, flowers, leaves and other plant parts, invertebrates, and vertebrates (such as squirrels, other small mammals, frogs, lizards, and birds). Capuchins are described as opportunistic foragers, whose manipulative abilities and strength help them obtain foods that are unavailable to other species. Their diet, however,

is broadly described as mainly fruit-based, whereas squirrel monkeys rely more heavily on insects. Still, what most characterizes the diet of these taxa is that it can drastically change according to the habitat, the season, or the availability of resources. For example, two neighboring groups of *C. capucinus* in Costa Rica could fit opposite dietary classifications, one being described as frugivorous (82% of their time spent feeding on fruit) and the other as insectivorous (44% of the time spent feeding on invertebrates) (Chapman and Fedigan 1990). Likewise, squirrel monkeys can subsist on a diet composed entirely of insects for short periods during seasons of food scarcity.

### Subfamily Aotinae (Genus *Aotus*)

Owl monkeys (*Aotus* spp.), also called *douroucoulis* or *mirikinás*, concentrate their activity during the night, with peaks at dawn and dusk; only one species, *A. azarae* *azarae*, shows cathemerality (i.e., intervals of activity can occur either during the day or during the night). Quantitative descriptions of feeding patterns for the strictly nocturnal species that range from Panama to Paraguay are scarce; however, studies of cathemeral owl monkeys in Argentina have provided some information on their diurnal diet. They are primarily frugivorous (45–66% of their time devoted to feeding on fruits), but they also can feed on leaves (15–41%), flowers (1–14%), insects, and fungi (Fernández-Duque 2011). However, given the difficulty to observe insect-eating in nocturnal and cathemeral primates, owl monkeys might be more insectivorous than reported.

### Subfamily Callitrichinae (Genera *Callithrix*, *Mico*, *Cebuella*, *Callibella*, *Callimico*, *Saguinus*, *Leontocebus*, *Leontopithecus*)

Marmosets (*Callithrix*, *Mico*, *Cebuella*, and *Callibella*), tamarins (*Saguinus*, *Leontocebus*, and *Leontopithecus*), and callimicos or Goeldi's monkeys (*Callimico*) include ripe fruits, floral nectar, and arthropods in their diet, but are mainly known for harvesting and eating plant exudates (e.g., gums and saps), which may account for up to 67% of yearly feeding time in pygmy

marmosets (*Cebuella pygmaea*) and 83% in buffy-headed marmosets (*Callithrix flaviceps*) (Digby et al. 2011). However, only *Callithrix*, *Mico*, and *Cebuella* have anatomical and dental specializations allowing them to scrap holes in tree bark to stimulate the flow of exudates. This ability to create feeding sites allows marmosets to exploit exudates year-round as a preferred resource. On the contrary, tamarins and callimicos do not possess these morphological features and only feed on exudates opportunistically. *Callimico goeldii* feeds on exudates seasonally, but despite earlier studies reporting only a minor consumption (1% of the annual diet), more recent data show that exudates can account for 20% of this species' feeding time in the dry season (Porter et al. 2009). Callimicos preferred resources, however, are jelly (*Auricularia* spp.) and bamboo (*Ascopolyporous* spp.) fungi, which are consumed year-round but are particularly important during the dry season (up to 63% of the monthly diet) (Porter and Garber 2010). Nonetheless, fungi seem to be a low-quality resource, with small amounts of sugar, fat, starch, calcium, and more than 80% of dry matter constituted by fiber.

Several callitrichines are known for forming mixed-species troops, also described as interspecific associations of two or more species that usually travel together and coordinate activities. *Saguinus fuscicollis* frequently associates with other species of the genus *Saguinus* and with *Callimico* and *Callithrix*. The associated species avoid feeding competition by using different forest strata and foraging techniques. For example, *S. fuscicollis* specializes in manipulative foraging, searching for prey in small and closed microhabitats such as tree holes and epiphytic bromeliads, whereas other *Saguinus* species prefer exploring open microhabitats using visual cues.

## Family Atelidae

### Subfamily Atelinae (Genera *Ateles*, *Lagothrix*, *Brachyteles*)

Spider monkeys (*Ateles* spp.) and woolly spider monkeys (*Lagothrix* spp.) are known as “ripe fruit specialists,” and their diet is very diverse in terms

of fruit morphospecies consumed. However, while fleshy fruits preferred by *Ateles* are generally lipid-rich, those preferentially selected by *Lagothrix* tend to be sugar-rich. Spider monkeys also include other plant parts such as flowers, leaves, petioles, and bark in their diet, and during certain seasons, young leaves can be an important resource in several dry forests or in fragmented landscapes (e.g., ~30% of feeding time in *Ateles geoffroyi* living in forest fragments in the Lacandona region of southern Mexico, Chaves et al. 2012). At several sites, spider monkeys are also observed to visit mineral licks (*salados*) to feed on soil. Instead, *Lagothrix* can complement its diet with insects.

Muriquis (*Brachyteles* spp.) are the largest atelines (males average 9.8 kg). Together with *Alouatta* spp., they are reported to be predominantly folivorous, with 41–93% of their monthly feeding time spent on mature and young leaves. However, the annual diet of *B. arachnoides* in a continuous forest in Southern Brazil comprised >70% fruits, although the consumption of leaves can be high in certain months when fruits are not available (Talebi et al. 2005). As in howler monkeys, the digestion of high amounts of foliage is favored by energy-minimizing behaviors, such as having small day ranges (~600 m), being inactive for many hours (at least 6 h/day), and spending few hours (~1 h) traveling during daytime (Milton 1984a).

#### Subfamily Alouattinae (Genus *Alouatta*)

Howler monkeys (*Alouatta* spp.), which are currently divided into 12 species, have the widest geographical distribution of all New World monkeys, ranging from Mexico to Argentina and inhabiting a variety of seasonal and nonseasonal habitats. They are considered, together with *Brachyteles*, the most folivorous platyrrhines, with a diet composed of leaves, fruits, flowers, and other plant parts. Howler monkeys possess certain anatomical, physiological, and behavioral traits associated to leaf-eating: a capacious colon compared to other members of the Atelidae family, where fiber fermentation occurs; a relatively long food transit time for their body mass (>20.4 h for *A. palliata*); molars with high

shearing crests that favor an efficient processing of fibrous leafy material; and long periods of rest, limited within-group social interactions, and a small day range (Milton 1984b). According to a recent review of the howler monkey diet (Dias and Rangel-Negrín 2015), the degree of frugivory and folivory may depend on rainfall patterns, group size, and forest size. In particular, howler species that live in wetter habitats and in larger forests tend to be more frugivorous and have a more diverse diet than species living in drier forests. An alternative interpretation, based on feeding rates rather than on the proportion of time spent feeding on different food types, has proposed three different dietary syndromes consistent with howler monkey phylogeny and biogeography (Garber et al. 2015). Specifically, howler monkeys from Mesoamerica (*A. palliata* and *A. pigra*) and *A. seniculus* would be characterized by a balanced leaf and fruit diet, Amazonian species (*A. belzebul* and *A. macconnelli*) by a fruit-enriched diet, and Atlantic Forest and southern howler monkeys (*A. guariba* and *A. caraya*) by a leaf-enriched diet.

### Family Pitheciidae

#### Subfamily Pitheciinae (Genera *Pithecia*, *Chiropotes*, *Cacajao*)

Sakis (*Pithecia* spp.) are the smallest pitheciines (1.7–2.4 kg), and fruits, usually unripe and with a hard exocarp, constitute more than 60% of their monthly diet (Norconk 1996). They also consume leaves, flowers, and insects and have been described as the most folivorous of the pitheciines given that leaves can constitute >8% of *P. pithecia* monthly diet (Norconk and Conklin-Brittain 2004). However, their distinguishing characteristic is that they are seed predators, and their dental morphology allows them to open hard fruit. Sakis share with other pitheciines several derived characters associated with their seed predation habits: robust canine teeth and styliiform lower incisors, which help remove the hard pericarp protecting seeds, and very flat molars, which help in the trituration of seeds characterized by a soft and uniform consistency (Garber and Kinzey 1992).

Also bearded sakis (*Chiropotes* spp.) obtain 72–97% of their diet from fruits and consume large amounts of mature and immature seeds. During periods of low food availability, their intake of seeds may diminish and instead shift to fleshy fruits. Their consumption of leaves is much more limited than saki's, but they feed more on arthropods, which occasionally are important constituents of their diet (up to 26% of the feeding records during a given month) (Veiga and Ferrari 2006). As in other pitheciines, the exploitation of structurally challenging items (e.g., seeds, hard fruits) is favored by their dental adaptations, which include flaring canines that aid in opening hard fruits and uneven dental enamel with bands that are useful during chewing and prevent tooth wear. Bearded sakis also have very robust mandibles compared to sakis, confirming their lower degree of folivory, which is correlated with limited jaw robusticity in platyrrhines.

*Cacajao*'s masticatory system is very similar to that of *Chiropotes*, thus allowing feeding on a wide range of hard fruit parts and species. Ripe and unripe fruits and fruit parts, including seeds, comprise more than 85% of the diet of *Cacajao* (Boyle et al. 2016), which can be complemented by leaves (3–4%) and insects (2–5%) (Norconk 2011).

### Subfamily Callicebinae (Genus *Callicebus*)

The diet of titi monkeys (*Callicebus* spp.) includes mainly fleshy fruits (50–82%), leaves (4–66%), and insects (0–20%) (Norconk 2011; Boyle et al. 2016). Compared to the other pitheciids, this genus is considered less of a seed predator, due to the lack of dental adaptations for feeding on hard fruits. However, they are known for feeding opportunistically on immature seeds when they are available.

## Platyrrhine Feeding Ecology

Despite representing a variety of specialized dietary niches, platyrrhines and the study of their diets and nutrition have made important contributions to our general understanding of primate feeding ecology and behavior. For example,

studies of atelines have provided insight into the processes driving food selection. Howler monkeys exhibit strong patterns of fiber and secondary metabolite regulation in which they limit intake of food items with high levels of fiber or secondary metabolites, often switching between food items to minimize the intake of a single secondary metabolite (Milton 1979; Glander 1982). Analogous patterns have subsequently been described in catarrhines. Similarly, the concept of nutrient balance suggests that primates attempt to reach nutritional targets by mixing food items to balance the intake of multiple nutrients as well as fiber and toxins. The first study to directly test for this strategy in a wild primate focused on fruit-specialist spider monkeys (*Ateles chamek*) and demonstrated that they maintain a constant intake of protein, while lipid and carbohydrate intake varies dramatically from day to day (Felton et al. 2009). Evidence for nutrient balancing has also been documented in other primate species around the world, including other platyrrhines.

In addition to nutritional demands, wild primates must also take into account social context when foraging. Experimental work with wild callitrichids has made valuable contributions to this area of the field. Specifically, it has improved our understanding of the extent to which information is shared among individuals in a group of foraging primates and has provided insight into individual foraging decisions within a finder-joiner paradigm (i.e., when to arrive first at a food resource vs. when to follow others) (Bicca-Marques and Garber 2005). Also, these experiments have facilitated the quantitative description of foraging costs and benefits for species participating in mixed-species foraging. Likewise, some of the first studies to focus explicitly on spatial patterns of movement through a habitat were performed on callitrichids (Garber 1989). This research suggested that instead of following sensory cues, wild primates utilize a mental map of their habitats to encounter food resources. However, these mental maps tend to be route-based, with the same routes centered on specific landmarks repeatedly utilized, instead of the shortest, most efficient travel paths from one tree to another.

Furthermore, for decades, tool use was believed to be present only in apes (Family: Hominidae). However, platyrrhines, specifically capuchins (*Cebus* and *Sapajus* spp.), are also adept tool users. In particular *Sapajus* spp. exhibit frequent tool use and are well-known for using stones to crack nuts (Otoni and Izar 2008). This information has broadened our understanding of the environments and contexts within which tool use occurs.

Finally, all mammals, including primates, possess a community of mutualistic microbes in the gastrointestinal tract that contribute to host digestive efficiency. The gut microbiota breaks down structural carbohydrates that are otherwise indigestible by the host, and it produces short-chain fatty acids that can be absorbed by the host and utilized for energy. The gut microbiota also produces vitamins such as B<sub>1</sub> and B<sub>6</sub> and can neutralize secondary plant metabolites (LeBlanc et al. 2013). While our understanding of the primate gut microbiota remains somewhat limited due to the relatively recent development of appropriate analytical techniques, the most comprehensive studies to date have focused on howler monkeys (*Alouatta* spp.) (Amato et al. 2016). These studies have indicated that different host species possess distinct gut microbial communities, and the gut microbiota can shift over time within individuals in response to changes in diet and physiology. Because different microbes utilize different metabolic pathways, these changes in the composition of the gut microbiota have the potential to strongly impact host nutrition, and these studies have incited similar research in a wide range of primate taxa.

## Conclusion

Platyrrhine diets represent a range of niches and specializations that are facilitated by both morphological and behavioral adaptations. Nevertheless, research on diets and foraging strategies of New World monkeys has provided important data from which to build a more

general knowledge of primate feeding and nutritional ecology.

## Platyrrhine Locomotion

Dionisios Youlatos

Department of Zoology, School of Biology,  
Aristotle University of Thessaloniki,  
Thessaloniki, Macedonia, Greece

## Definition

Body displacement relative to physical surroundings in New World monkeys.

## Introduction

Locomotion, i.e., body displacement within space and time, is part of a behavioral continuum with postures, involving minimal to no body displacement, that enables animals to interact with and utilize their environment. As such,

locomotion is an integral part of animal biology, as it provides access to food sources, facilitates social contact and bonding, promotes mate connection and ritual, and enables escape from potential predators. In this way, it feeds back to important biological parameters and contributes significantly to fitness. Locomotion can be seen as the response of morphology (e.g., physiology, anatomy) to the architectural challenges of the environment (substrate availability, size, inclination, texture, stiffness etc.). Thus, terrestrial mammals transfer their body mass on the ground mainly by walking, running, and jumping (but some terrestrial mammals, which live in rocky habitats, can also rock climb). On the other hand, arboreal mammals, having to deal with the irregular three-dimensional environment of forest canopies, tend to display a remarkable diversity of different locomotor modes. In Primates, a well-nested arboreal mammalian order, locomotion has played a fundamental role to the major evolutionary radiations, as well as to the origins of the order itself. The great diversity of locomotor modes encountered in primates (as in other mammalian orders as well) is better termed as locomotor behavior, and its qualitative and quantitative description contributes to the understanding of evolutionary and ecological adaptations of modern and fossil primates. In terms of locomotor behavior, platyrrhines, the monkeys of the New World, exhibit one of the most astounding diversities among primates, from squirrel-like scampering to ape-like arm swinging, involving the evolution of the unique prehensile tail, acting as a fifth limb! The variable ways that platyrrhines have evolved in order to negotiate different habitats also seem to characterize the different evolutionary radiations within the group. In this way, this diversity has contributed to their differentiation into very specific eco-evolutionary niches and has enabled them to exploit a variety of habitats that promoted their expansion across Central and South America.

## Setting the Context

As locomotion in primates is basic for elucidating their evolutionary adaptations, it is important to understand the context of this chapter. In this way,

the present chapter explores the locomotor diversity of platyrrhines by surveying the locomotor profiles of the different families, subfamilies, and genera, in cases where substantial diversity is in play. Considering that the platyrrhine phylogeny is still under debate, a fact beyond the scopes of this entry, we shall opt for a rather conservative classification, accepted and used by the experts (Perez and Rosenberger 2014). Thus platyrrhines are divided into three families: (i) Pitheciidae (uakaris, sakis, and titi monkeys), (ii) Atelidae (the prehensile-tailed monkeys), and (iii) Cebidae, composed of the subfamilies Callitrichinae (the clawed marmosets and tamarins) and Cebinae (capuchin, squirrel, and owl monkeys). Moreover, as locomotion is the morphobehavioral response to the mechanical constraints of the environment, we shall only consider those studies that have considered this behavior in the wild, and in case of lack of comparable data, in large enclosures, where the animals can freely move. Fortunately, platyrrhines are relatively well studied in this domain and there are comparable data for many species.

## Pitheciidae

The family Pitheciidae is composed of four genera: *Pithecia* (saki); *Chiropotes* (bearded saki); *Cacajao* (uakari), which are grouped in a single subfamily, the Pitheciinae; and *Callicebus* (titi monkey), representing its own subfamily, the Callicebinae. The locomotor repertoire of these monkeys is rather generalized and is dominated by quadrupedal walking, running, and bounding on top of horizontal and moderately inclined branches, as well as leaping in between tree crown peripheries and hopping across branches (Fig. 1). Among them, sakis appear to be the most saltatory, and more particularly the white-face saki *Pithecia pithecia*, of which, more than half of its locomotor repertoire is represented by different forms of horizontal leaps and hops (Fleagle and Mittermeier 1980; Walker and Ayres 1996). In contrast, the monk saki *P. monachus* differs in being more quadrupedal (Youlatos 1999), underscoring the locomotor flexibility of the

**Platyrrhine Locomotion, Fig. 1** Proportions of major locomotor modes in the Pitheciidae (*QWR* quadrupedal walk and run, *CL* vertical climb and clamber, *L* leap and hop, *S* bridging and suspensory locomotion)

genus (Walker 1993). Quadrupedal activities, involving walking along single horizontal or moderately inclined branches, climbing up and down along vertical or steep branches, and clambering towards all directions across multiple flexible branches also appear to be the dominant locomotor modes for the bold uakaris *Cacajao calvus*, despite the fact that they also use leaping between tree peripheries rather frequently (Walker and Ayres 1996). Bearded sakis *Chiropotes satanas* also rely mainly on quadrupedal walking and running and to a lesser extent on leaping and climbing (Fleagle and Mittermeier 1980; Walker and Ayres 1996). The other member of the family, titis (*Callicebus* spp.), which probably represents the basal member of this clade, is basically quadrupedal (walking, running, bounding) with variable, but generally moderate, rates of leaping behavior (Youlatos 1999; Lawler et al. 2006). What is remarkable about the locomotor repertoire of the family is that it appears to approximate that of the ancestral platyrrhine. In effect, there is a consistent pattern of quadrupedal walking-running-bounding behavior with some variable component of leaping and hopping activities when comparing

the reconstructed locomotor behavior of fossil Pitheciinae with the behaviors of extant forms. All fossil representatives tend to exhibit a repertoire resembling that of *Callicebus* and *Chiropotes*, i.e., quadrupedalism accompanied by leaping. In fact, if *Callicebus* represents in some form the morphological and behavioral prototype of ancestral platyrrhines (Ford 1988), then all these modern monkeys do not appear to have changed much since the inception of the pitheciine radiation. Within this radiation, only *Pithecia*, and more particularly, *P. pithecia* seem to depart far from this blueprint. *Cacajao* also partly differs, as it evolved in Amazonian flooded forests with quite discontinuous canopies that apparently encouraged increased leaping activities (Walker and Ayres 1996).

## Cebinae

The subfamily Cebinae, of the family Cebidae, contains two very widely known monkeys, the squirrel monkeys (*Saimiri*) and the capuchins (genera *Sapajus* and *Cebus*), and one less known,

**Platyrrhine Locomotion, Fig. 2** Proportions of major locomotor modes in the Cebinae (*QWR* quadrupedal walk and run, *CL* vertical climb and clamber, *L* leap and hop, *S* bridging and suspensory locomotion)

the owl monkey (*Aotus* spp.), the only nocturnal monkey. Given this disparity, there appears to be a strong bias in the study of the locomotion of capuchin and squirrel monkeys over owl monkeys. In fact, there are no detailed data on the locomotion of *Aotus*, but anecdotal descriptions and predictions from skeletal traits suggest a mainly quadrupedal monkey with moderate leaping activities (Wright 1989). This behavioral repertoire appears to bear strong similarities to that of titis (*Callicebus*) and is further supported by skeletal similarities between the two monkeys (Ford 1988). On the other hand, there are field data on three different *Saimiri* species and all show that squirrel monkeys are primarily quadrupedal walkers and runners, as well as leapers (Fig. 2). Among them, the common squirrel monkey *S. sciureus* seems to be the more saltatorial, using long acrobatic leaps between the terminal branches of tree crowns (Fleagle and Mittermeier 1980; Youlatos 1999). A comparable locomotor profile is exhibited by the black-capped squirrel monkey *S. boliviensis*, which also uses considerable leaping, but is mainly quadrupedal (Fontaine 1990). On the other hand, the red backed squirrel monkey *S. oerstedii* of Central

America is the more quadrupedal of all (Boinski 1989). Quadrupedalism along and across branches and horizontal leaping between tree crowns seem to suit the predacious omnivory of squirrel monkeys that travel fast and range in many forest types exploiting all forest strata. The larger representatives of this clade, the gracile capuchins (*Cebus* spp.) and the robust capuchins (*Sapajus* spp.) appear to be rather consistent in their locomotor patterns (Fig. 2). Available field data on three species of gracile capuchins and one species of robust capuchins indicate increased quadrupedal activities, coupled with variably significant rates of leaping and moderate climbing and clambering. In effect, the robust brown capuchin monkey (*Sapajus apella*) appears to mainly walk and run quadrupedally along single branches, to regularly perform acrobatic leaps between tree tops, and to a lesser extent climb along steep and vertical branches and clamber across small intertwined branches (Fig. 2); moreover, these monkeys also use considerable amounts of bridging between tree crown gaps and suspensory quadrupedal locomotion below branches with the aid of the semi-prehensile tail (Youlatos 1998;

Wright 2007). On the other hand, the gracile capuchins seem to rely more on quite high rates of quadrupedal locomotion and slightly less on leaping and climbing and clambering, but show much less below-branch suspensory behaviors (Gebo 1992; Youlatos 1999; Bezanson 2009). These locomotor repertoires seem to suit the adaptive profile of the generalist capuchin, as a particularly agile, inquisitive and destructive omnivore, which exploits all forest strata, ground included, in a remarkable variety of habitats, resulting in nearly one of the most expanded geographical ranges among all New World monkeys (Rosenberger 1992). Unfortunately, there are no relevant fossils with associated skeletal elements in order to directly assess any evolutionary trends within this particularly interesting clade, but it is safe to assume that these medium-sized monkeys have preserved a largely generalized locomotor behavior.

### Callitrichinae

This group of platyrrhine monkeys is unique as they have secondarily developed functional

claws, analogous to those of other clawed mammals, and they are among the smallest New World monkeys. The clade is informally divided into two groups: the tamarins and the marmosets (probably including callimicos). The former group is composed of the highly diversified Amazonian genus *Saguinus* and the less diversified, but very specialized, genus *Leontopithecus* of the Atlantic forests of Brazil. Field observations on several Amazonian tamarin species indicate that they intensively use quadrupedal walking and bounding along single horizontal and moderately inclined branches, coupled with high rates of horizontal leaping between terminal branches of tree crowns (Fig. 3; Garber 1980, 1991; Garber and Leigh 2001; Youlatos 1999; Youlatos and Gasc 2001). On the other hand, they seem to rely less on their clawed extremities, as clawed, squirrel-like, locomotion along medium- and large-sized vertical branches and trunks is variable across species, but less common in general. These locomotor patterns indicate that tamarins still exploit the small-branch milieu of tree peripheries to a great degree. Nevertheless, the use of clawed activities on large vertical supports also demonstrated their

**Platyrrhine Locomotion, Fig. 3** Proportions of major locomotor modes in the Callitrichinae (QWR quadrupedal walk and run, CL vertical climb and clamber, L leap and hop, CC clawed locomotion)

dependence on gums and bark insects, but to a lesser degree compared to that of the marmosets. Unfortunately, there are no detailed field observations on the locomotion of the highly specialized lion tamarins (*Leontopithecus* spp.) of the Brazilian Atlantic forests. The morphology of the genus indicates an adept manipulative forager for non-mobile prey and fruit, as well as seasonal dependence on gum feeding. Studies in large zoo enclosures suggest reliance on quadrupedal activities coupled with leaping behavior (Karantanis 2010). Similar positional patterns would likely facilitate and go well with the intensive manipulative exploitation of the discontinuous canopy of all forest levels that lion tamarins generally exploit.

On the other hand, field data on the locomotion of the radiation comprising the callimico and marmosets are relatively scarce. Callimicos (*Callimico goeldii*) are morphologically very specialized monkeys and this is also reflected on the particularly high rates of leaping, most of which are leaps from and to vertical branches, trunks, or bamboos; quadrupedal walking and bounding locomotion along horizontal and moderately inclined branches and clawed locomotion on large vertical substrates are used in a much lesser degree (Fig. 3; Garber and Leigh 2001). These locomotor patterns appear to be ecologically associated with the exploitation of the lower strata of Amazonian forests, with abundant vertical substrates, where callimicos frequent forage for arthropods and collect fruit and fungi. The marmosets, *Cebuella*, *Mico*, and *Callithrix*, are by far the most ecologically specialized callitrichines, as they exploit large vertical branches in relation to their tree gouging habits and year-round exudate feeding (Garber 1992). The exploitation of this specialized niche has compelled analogous locomotor behaviors. Thus, the Amazonian pygmy marmosets *Cebuella pygmaea*, the smallest representative of the group and of all New World monkeys, appears to use very high rates of claw-climbing on large vertical branches and trunks, as well as frequent leaping, including high rates of leaps in between vertical substrates (Fig. 3; Youlatos 2009). Unfortunately, there are no field locomotor observations on the other highly

diversified Amazonian marmosets (genus *Mico*). This is also the case for the Atlantic forest marmosets (genus *Callithrix*). The only available data concern the locomotion of common marmoset *Callithrix jacchus*, but not in its natural habitat. These observations indicate that common marmosets emphasized on clawed locomotion on large vertical trunks and branches, and quadrupedal walking and bounding along horizontal and moderately inclined branches, and used a considerable proportion of horizontal leaps between tree peripheries (Fig. 3; Zaluar et al. 2013). These observations suggest different locomotor strategies across the different clades of the Callitrichinae. The prevalent combination of quadrupedalism and leaping implies this pattern as that of the common ancestor of the group and very likely shared by the other members of the Cebidae, as well! In effect, leaping is commonly present in all callitrichine clades but has differentiated into extensive vertical leaps only in callimicos and marmosets. On the other hand, quadrupedal activities have significantly reduced in callimicos and pygmy marmosets, but lack of comparable data on other marmosets provides no clues for further assumptions. Finally, vertical clawed climbing, although used at variable rates, tends to be particularly important for *Callithrix* and *Cebuella*, which are ecologically highly dependent on gum feeding.

## Atelidae

This family comprises the largest and more diversified New World monkeys. All atelids share a fully functional prehensile tail and the variable use of forelimb and hind limb suspensory locomotion. They also represent the group which is best studied in terms of locomotor behavior. The howler monkeys (*Alouatta* spp.) include the smallest, as well as some of the largest, species among the atelids and have been well studied across their range from Central to southern South America. In evolutionary terms, howler monkeys appear to have differentiated earlier than the other genera (they comprise their own subfamily, the Alouattinae) and their locomotion

is characterized by a preponderance of quadrupedalism (Fig. 4). This involves quadrupedal walk along horizontal or inclined single branches, climbing along vertical branches, and clambering across multiple twigs, as well as substantial bridging between tree gaps and suspensory locomotion involving the forelimbs but mainly the hind limbs and the prehensile tail (Youlatos and Guillot 2015). The howler species that inhabit the northern and southern edges of howler range appear to rely more on quadrupedal activities and less on suspensory locomotion. In contrast, Amazonian howler species, of which locomotor observations are available, tend to display a more suspensory and much more clambering and climbing repertoire. The remaining three extant genera (*Lagothrix*, *Ateles*, and *Brachyteles*) compose the other subfamily, Atelinae, and appear to show a gradient of increasing degrees of suspensory locomotion (Fig. 4). Woolly monkeys (*Lagothrix* spp.) are intermediate using significant amounts of quadrupedal walk and vertical climb along single branches and clamber across multiple smaller branches, as well as considerable

rates of forelimb and tail-assisted suspensory locomotion below branches (Cant et al. 2001). During these suspensory bouts, woolly monkeys tend to keep their body in a pronograde (more or less horizontal or slightly inclined) position, which is completely different from the forelimb tail-assisted suspensory locomotion of spider monkeys (Cant et al. 2003). In fact, spider monkeys (*Ateles* spp.) tend to keep their body more or less orthograde (vertical) and rotate it when they travel in a suspensory manner (comparable to the brachiation of gibbons), but they also use suspensory locomotion in higher and significant proportions (Youlatos 2008). Quadrupedal walk, climb, and clamber are represented in much lower rates; however, subtle locomotion differences exist between spider species, with the Central American Geoffroy's spider monkeys (*A. geoffroyi*) being less suspensory than the Amazonian species (e.g., *A. paniscus* and *A. belzebuth*). Unfortunately, there are no detailed locomotor study for the Atlantic forest woolly spider monkeys (*Brachyteles* spp.), although anecdotal observations coupled with morphological analyses

**Platyrrhine Locomotion, Fig. 4** Proportions of major locomotor modes in the Atelidae (*QWR* quadrupedal walk and run, *CL* vertical climb and clamber, *L* leap and hop, *S* bridging and suspensory locomotion)

indicate increased forelimb tail-assisted suspension, similar to that of spider monkeys (Rosenberger and Strier 1989). It appears that as the atelines evolved, they apparently became more suspensory in order to forage more efficiently and cover longer distances in search of sparsely dispersed food sources, and tail-assisted forelimb suspension is a unique locomotor specialization that greatly facilitates canopy travel. The phylogenetic relationships between these three suspensory taxa have not been resolved yet, but it seems that spider monkeys are the sister taxon of both woolly and woolly spider monkeys. If this holds true, this relationship implies that the forelimb-dominated suspensory locomotion evolved in parallel in *Ateles* and *Brachyteles*, whereas *Lagothrix* assumed a different locomotor profile, involving relatively high rates of quadrupedal walk, climb, and clamber in relation to its mixed frugivorous and animalivorous regime (Jones 2008).

## Conclusion

Platyrrhine locomotion is highly diversified. It ranges from arboreal quadrupedal walk and run on top of single horizontal and moderately inclined branches within the tree crown, vertical claw climbing along large trunks or branches in the central parts of tree crowns, to fast forelimb tail-assisted suspensory locomotion below branches within and across tree tops. The proportions of these different modes and the way they are performed have shaped the main platyrrhine radiations that evolved into divergent ecological niches and have contributed to the successful exploitation of the great variety of microhabitats within the different forests across Central and South America.

## Definition

*Platyrrhini* – primate suborder that includes all New World or Neotropical monkeys (primates naturally found in the Americas from northern Mexico to southern Brazil and northeastern Argentina). There are 173 species of platyrrhines distributed into 21 genera belonging to five families: Cebidae (capuchin monkeys and squirrel monkeys), Callitrichidae (marmosets, tamarins, and Goeldi's monkeys), Aotidae (owl monkeys), Pitheciidae (titi monkeys, saki monkeys, cuxius, and uakaries), and Atelidae (howler monkeys, spider monkeys, woolly monkeys, and muriquis).

## Introduction

Sensory systems play an essential role in an organism's perception of its surroundings, including the physical and chemical properties of its habitat as well as its conspecifics (individuals of its own species) and those individuals of other interacting species. In the case of primates (prosimians, New World monkeys, Old World monkeys, and apes), the senses of vision, olfaction, and hearing enable individuals to navigate in

their habitats, find their food, avoid predators, and interact with other members of their own species or other species.

## Platyrrhines

Arboreality (tree-living) and frugivory (fruit-eating) characterize all platyrrhines. However, they show large differences in other aspects of their biology. Platyrrhines range in size from the tiny dwarf (*Callibella*) and pygmy (*Cebuella*) marmosets whose adult weight does not exceed 120 g, to the large woolly spider monkeys (*Lagothrix*) and muriquis (*Brachyteles*) that may reach 10 kg. The size of their social units (groups) ranges from the small family groups composed of four to five individuals (an adult couple and their immature offspring) characteristic of the monogamous titi monkeys (*Callicebus*, *Plecturocebus*, and *Cheracebus*) and owl monkeys (*Aotus*) to large multimale-multifemale groups containing up to 100 or more uakaries (*Cacajao*). Whereas pygmy marmoset groups may exploit home ranges of just about 1 ha, spider monkey (*Ateles*) and woolly spider monkey groups may range over about 1,000 ha. Platyrrhines complement their diets mostly with leaves, flowers, animal prey, or exudates (gums).

Platyrrhines show a wide range of within- and between-group communication channels, including complex vocalizations, scent marks, and age-related sexual differences in face or body color. These traits, together with their diet composition and foraging strategies, home range size, and the identity and density of their potential predators, represent important selective pressures that have shaped their sensory systems.

Most platyrrhines live in closed-canopy forests, but some species inhabit more open-canopy woodland habitats in the Cerrado and Caatinga biomes. These structural habitat differences influence the usefulness and range of accuracy of some sensory systems. Whereas a habitat's characteristics do not affect the range of accuracy of the senses of taste and touch, they affect the senses of vision, olfaction, and hearing. For instance, the usefulness of vision is about 20–30 m within a

closed-canopy forest, whereas the usefulness of olfaction may extend to about 200 m and that of hearing probably up to 2,000 m (Dominy et al. 2001). The boundary for vision in the open-canopy habitats of the Cerrado and Caatinga is certainly much wider.

## Platyrrhine Sensory Systems

Little has been investigated about the role of the senses of taste and touch in platyrrhine behavior. Taste may help platyrrhines to select food items and to avoid the ingestion of harming amounts of the same secondary plant metabolites. These toxic or digestion-inhibitor chemicals are mainly found in mature leaves and unripe fruits. The lack of information on whether howler monkeys (*Alouatta*), the most folivorous platyrrhines, are capable of making such discriminations compromises the understanding of the role of taste in their foraging behavior. However, compared to the frugivorous spider monkeys, howlers have less fungiform papillae in their tongues and less taste buds in their oral cavity, suggesting a poorer capacity to detect taste stimuli (Hernández-Salazar et al. 2015).

Touch plays an essential role in all kinds of platyrrhine locomotion. In addition to the importance of this sense in the hands and feet of all platyrrhines, touch is also well developed in the naked skin of the inferior distal third of the prehensile tail of atelids. Touch also contributes to postural behavior, social interactions such as grooming, and food gathering, manipulation, and selection. The role of touch in food selection varies among species. For instance, it is more important for squirrel monkeys (*Saimiri*) than for spider monkeys (Laska et al. 2007). Tactile information is also critical for callitrichids foraging for prey in blind microhabitats (that is, locations where foragers cannot see the content, such as tree holes and the interior of bromeliads). The importance of touch during foraging may have reached its maximum development among platyrrhines in capuchin monkey tool use.

## Vision

Early in primate evolution, a forward rotation of the eyes allowed for stereoscopic vision and a greater reliance on sight. Platyrrhines, like other anthropoid primates, enjoy a high visual acuity. On the other hand, whereas both female and male Old World monkeys and apes are capable of making true color discriminations in the red, green, blue, and yellow spectra (i.e., they are trichromats), platyrrhines present both between- and within-taxa differences in this capacity. While howler monkeys are the only platyrrhines that have evolved a routine trichromacy equivalent to that found in the other anthropoids, all other diurnal New World monkeys present a color vision polymorphism. Most females are also trichromats, but all males and some females are unable to discriminate colors in the red-green axis (that is, they are dichromats). Yet, the nocturnal owl monkeys are monochromats and lost the capacity of seeing colors.

Color vision arises from the neural comparison of the activity produced by different retinal photoreceptors (i.e., rods and cones). Primates have only one type of rod and usually several types of cones. While rods function only under low light conditions, usually during the night, cones are useful at daytime under higher luminosity. The action of cones allows primates to see in colors, and the interaction between rods and cones under intermediate light conditions may improve this ability. Platyrrhines have two genes that encode cone visual pigments. One gene, located in an autosomal chromosome, encodes the short-wavelength (blue) pigment. The other, located in the X chromosome, encodes the medium-wavelength (green) or long-wavelength (red) pigments and has many alleles. Therefore, with the exception of the trichromat howler monkeys and the monochromat owl monkeys, heterozygous platyrrhine females are trichromats, displaying a color vision ability similar to that of normal humans. On the other hand, homozygous females and all males are dichromats and have a color vision roughly equivalent to that of red-green color-blind humans. The frequencies of the alleles of the X gene in a given population affect its

proportion of trichromats and dichromats (Carvalho et al. 2017).

There are two main hypotheses for the evolution of primate color vision. The heterozygote advantage hypothesis suggests that trichromat individuals save time and energy spent in fruit foraging by detecting nutrient- and energy-richers conspicuous ripe fruits at longer distances than do dichromats. This improved detection would favor the fixation of a higher diversity of green-red pigment alleles by increasing the breadth of fruit phenotypes found at the group level (Mollon et al. 1984). The folivory hypothesis also focuses on the advantage of heterozygotes. However, it argues that the discrimination of conspicuous protein-richers, less fibrous, and less toxic younger leaves from the greenish background of protein-poorer, more fibrous, and more toxic mature leaves was the major pressure selecting for the emergence of trichromatic color vision. The fact that the highly folivorous howler monkeys are the only New World primate taxa to show routine trichromacy is compatible with this hypothesis, although the potentially highly folivorous muriquis are also polymorphic. There is also behavioral evidence for the importance of trichromacy especially in the long-range detection of conspicuous fruits (Melin et al. 2017) and predators (Pessoa et al. 2014) and for the advantage of dichromats in the detection of cryptic insect prey (Melin et al. 2007).

A balance between these trichromat and dichromat advantages better accounts for the evolution and maintenance of this poly-allelic platyrrhine visual polymorphism in all diurnal taxa except howler monkeys. The mechanisms of kin selection, mutual benefit of association, or niche divergence may independently or in combination favor this balance (Melin et al. 2008; Mollon et al. 1984). According to the kin selection hypothesis, members of family groups (e.g., marmosets and tamarins) containing dichromats and trichromats enhance their fitness (both direct and inclusive) by taking advantage of the detection of a wider range of predators and food resources. This improved foraging is also at the core of the mutual benefit of association hypothesis, by which the monitoring of kin and nonkin group mates with diverging color vision abilities allows the exploitation of

a richer diet. Finally, the color vision polymorphism may reduce within-group competition for resources if the aforementioned advantages translate into niche divergences between trichromat and dichromat individuals, such as in the preference for different food items or vegetation strata for foraging.

Irrespective of how colorful a platyrrhine sees the world, vision plays a crucial role in foraging, predator avoidance, spatial navigation, and social communication. Although diurnal platyrrhines rely more on visual cues for finding feeding patches and distinguishing food from nonfood items than owl monkeys (Bicca-Marques and Garber 2004), vision is also an important sense for these nocturnal platyrrhines. Owl monkeys travel farther and monitor potential feeding sites more frequently around dusk and dawn, in full or bright moon nights and during periods of stronger moonlight (Wright 1989). The ability to distinguish potential predators from non-predator animals allows platyrrhines to react appropriately and avoid sparing time and energy in unnecessary escape or mobbing strategies. Platyrrhines also use the sense of vision for choosing male and female mates based on physical characteristics, such as body size and color (Moreira et al. 2015). Body displays used in interspecific interactions and in within- or between-group affiliative, sexual, or agonistic contexts also characterize the behavioral repertoire of all platyrrhines.

## Olfaction

The sense of smell is useful for helping to locate rich, out-of-sight sources of odoriferous foods (e.g., flowers and fruits), selecting specific food items to ingest, locating hidden prey, getting information on the reproductive status or social rank of conspecifics, and detecting predators. The reliability of the sense of smell decreases with an increasing distance from the odor source(s). Wind speed and wind direction affect the spatial differences in odor concentration resulting from the diffusion of the odor plumes. In the case of the navigation between feeding patches, the size and

height of the tree crown and the existence of other sources of the same food nearby also influence the effectiveness of the use of the sense of smell (Garber and Hannon 1993).

Captive squirrel monkeys can use the sense of smell to choose objects associated with food and may remember their odors for more than 30 weeks, a memory similar to that of humans (Laska et al. 1996). The highly frugivorous spider monkeys appear to smell unripe fruits at a greater extent than ripe fruits, whereas the senses of touch and taste are more significant in the final, in-hand selection of ripe fruits (Pablo-Rodríguez et al. 2015). However, olfactory cues play a minor role in foraging decision-making when a platyrrhine is within a feeding patch but is not holding a food item. In this respect, owl monkeys are an exception among platyrrhines as they improve their within-patch foraging success by relying on food-related olfactory cues (Bicca-Marques and Garber 2004). In addition to the fact that the low light conditions of the night greatly reduce the usefulness of visual information, odors are stronger, diffuse more slowly, and last longer in the more humid and less windy nighttime atmosphere. Therefore, these nocturnal platyrrhines may also use odor cues to mark and track commonly used travel routes (Wright 1994).

Olfaction is also involved in scent-marking behavior. Platyrrhine scent-marking is believed to function in the transmission of information on the marking individual's quality as a potential mate or as an advertisement of its quality as a competitor to same-sex conspecifics or both (Heymann 2006). Platyrrhines may have odor glands distributed in different body regions. Callitrichids (marmosets and tamarins) are known for their frequent marking behavior with circumgenital (or anogenital), suprapubic, and sternal scent glands (Epple et al. 1993). The highly exudativorous marmosets *Callithrix jacchus* and *C. penicillata*, for example, often leave their individual scents in gouged tree holes by rubbing their circumgenital region.

Platyrrhines may also recognize the smell of predators. Even naïve individuals have been shown to react to the odor of potential predators. For instance, captive-born tamarins (*Saguinus*

*labiatus*) with no experience with encountering predators reacted more strongly to the scent of predator feces than to the scent of feces of non-predators. Specifically, the tamarins sniffed and avoided more predator than non-predator fecal extracts (Caine and Weldon 1989). This ability to discriminate between danger-related and innocuous odors has important implications for the management of captive monkeys. Zoo monkeys may experience higher levels of stress if there are predators in nearby enclosures, as has been found for other mammals (Morgan and Tromborg 2007). On the other hand, if these monkeys become over-habituated to the odor of predators because they do not represent actual dangers in captivity, they may stop to appropriately react to them. Whereas the reduction or elimination of these behavioral responses to predator odors may improve a monkey's well-being in captivity, the survival of over-habituated zoo specimens is likely to be greatly compromised if they are returned to the wild.

## Hearing

Platyrrhines integrate the auditory and visual systems to locate calling or moving prey during foraging. This ability is likely to be particularly important for the omnivorous nocturnal owl monkeys (Wright 1989), although captive individuals have failed to locate hidden food rewards (banana slices) based solely on their association with an artificial auditory stimulus (a 25-dB ticktack) in the unique experimental study testing this ability so far (Costa and Bicca-Marques 2014). The sound of moving and calling predators or other potential sources of danger also elicit escape responses by all platyrrhines. This use of hearing is well known by researchers that are in the process of habituating their study subjects (that is, "training" the monkeys to stop reacting to the observer's presence).

While little is known about the relative importance of auditory cues in platyrrhine prey foraging and predator avoidance compared with information processed by the senses of vision and olfaction, the role of vocalizations in intra- and intergroup communication has long been an

attractive research topic. All platyrrhine taxa emit simple or complex species-specific calls varying in frequency, duration, amplitude, pitch, and composition that influence their likelihood of experiencing attenuation, reverberation, distortion, or other acoustic disturbances caused by the abiotic factors and the biotic noises of their forested habitats (Brown and Waser 2017). The hearing capacity of an individual depends on the distance between its ears (a trait directly related to its body size) and the characteristics of its auditory system. This capacity relates directly with the frequency of species-specific calls, their functions, and the size of the home range (i.e., the space used by a social group during a given time, such as a year).

Platyrrhine vocalizations include food calls; resource, mate, and territorial defense calls; contact and distress calls; and predator alarm calls, among many others. These vocalizations normally change with aging and may vary or not between females and males (Snowdon 2017). Contact calls are important for all platyrrhine individuals and are obviously critical for owl monkeys. Most callitrichids may emit food calls upon the arrival at productive sources. Callitrichids involved in mixed-species associations, such as the tamarins *Saguinus mystax*, *S. labiatus*, or *S. imperator* with *Leontocebus fuscicollis* or *L. weddelli*, give specific predator alarm calls to terrestrial, aerial, or arboreal predators. Regardless of the calling species, the members of both associated taxa recognize and appropriately respond to these calls.

Duetting by the breeding pair is a hallmark of the monogamous titi monkeys, although they also emit solos and group choruses. All these vocalizations are emitted mostly in early morning. Titi monkeys use loud calls for between-group communication aiming the defense of important food sources, mates, or territories (Caselli et al. 2014, 2015). The enlarged hyoid bone of howler monkeys, particularly adult males, enables them to produce their characteristic howl or roar. Howls may promote intergroup space regulation, but may also play a role in maintaining group cohesion, attracting females, avoiding predators, and mediating male-male or intergroup competition

(Kitchen et al. 2015). The vocal repertoire of muriquis include screams emitted by lone individuals, barks emitted during stressful situations, and the amazing neighs (or whinnies), similar to horse ones, used as contact calls especially during travel or lone feeding (Nishimura et al. 1988).

## Play Behavior

Sergio M. Pellis and Vivien C. Pellis  
Department of Neuroscience, University of  
Lethbridge, Lethbridge, AB, Canada

### Introduction

The occurrence and value of play in humans, especially as it relates to developmental processes, has been intensively studied (Smith 2010). In contrast, the study of play in nonhumans has had a more checkered history, really only getting serious attention from the 1970s onwards (Burghardt 2005). Moreover, this research has

tended to fall into two broad camps with little or no overlap: experimental studies, mainly on rats, have focused on the neurobehavioral mechanisms involved in producing play (e.g., Siviý 2016), and observational studies, on a broader diversity of species, of captive, semi-captive, and free-living animals have focused on the functions of play that may have been important for its evolution (e.g., Martin and Caro 1985).

Recently, both these strands of research have gained sufficient maturity that major works have appeared integrating these divergent fields while also attempting to unify studies of human and nonhuman animals (e.g., Burghardt 2005; Pellegrini 2011; Pellis and Pellis 2009). Recent special issues of journals devoted to play illustrate the progress that can be achieved when researchers from multiple disciplines talk to one another (e.g., *American Journal of Play*, 7(1), 2014; *Animal Behavior & Cognition*, 1(2), 2014; *Adaptive Behaviour*, 23(6), 2015; *Behaviour*, 153(6/7), 2016; *Current Biology*, 25(1), 2014). Indeed, there are glimmers of a comprehensive model gradually taking shape. Still, for all the progress that is evident in comparative analyses of play, it is important to take stock as to what we know or think we know, identify the key intractable issues, and characterize the questions and methods most likely to be fruitful in the coming decades.

### Defining Play

The first big problem to resolve is that of defining the phenomenon in question. There have been many attempts at defining play (Fagen 1981). These have, to varying degrees, included such distinguishing features as play being autotelic (i.e., done for its own sake), voluntary, and as having no immediate function. As much of the content of play is derived from behavior seen in other functional contexts such as sex, aggression, predation, and antipredator behavior, it is these characteristics that emphasize how the behavior is performed and the context in which it is performed that are critical for distinguishing play from its nonplayful counterparts (Heymer 1977).

These characteristics make actions that are performed during play playful rather than serious, but the application of such criteria tends to be subjective.

The subjectivity inherent in identifying play has led to disputes over what is and is not play. For example, even though the competitive interactions of immature cockroaches appears to be autotelic, with the behavior patterns typical of serious fighting being performed in a way that does not lead to the outcomes typical of aggression, the behavior is not deemed to be play (Fagen 1981). Similar interactions with these properties, involving two puppies or two kittens, would near universally be labeled as play. Indeed, even the mainstay of neurobehavioral research on play, the laboratory rat, had its juvenile play-like social behavior labeled immature aggression by some researchers, until the neurobiological evidence became overwhelming that play involves different behavior and engages distinct, neural mechanisms compared to aggression (Pellis and Pellis 2009). The more animals are like us, the more likely is their autotelic behavior to be labeled as play.

Burghardt (2005) developed a definition of play involving five criteria to lessen the impact of such subjective judgments. To qualify as play, the behavior in question has to (1) be incompletely functional in the context expressed, (2) be voluntary or rewarding, (3) be, in some ways, modified developmentally or structurally compared with when it is used in its normal, functional context, (4) be performed repeatedly, but not necessarily in an invariant form, and (5) be initiated by healthy, relatively unstressed animals in a relaxed context. Two things distinguish this criteria-based definition from earlier definitions. First, it includes all the major criteria that were grouped together in different ways in previous definitions, and it requires that all need to be met before the conclusion is drawn that the behavior in question qualifies as play. This greatly reduces the importance of the observer's "gut feeling" when making this decision. Second, the criteria can be met to varying degrees: one species may just minimally make the grade,

whereas another may greatly exceed that minimum. This latter issue is particularly important to diminish our mammal-centric biases. Indeed, using these criteria, behavioral sequences from a wide range of nonmammalian species, including nonvertebrate ones, have been categorized as play (Burghardt 2005; Pellis et al. 2014).

Another important contribution of this multi-criteria definition is that it has provided a way to distinguish, objectively, play from other behaviors that have often been confounded with play, such as stereotypies and exploration (Burghardt 2005; Pellis and Burghardt 2017). The advent of this definition, however, has not completely solved the problem of unambiguously distinguishing play. Two of the criteria are particularly problematic. While traditionally neglected as a subject of study, play in some species continues into adulthood and adults can use play in a variety of contexts that confer immediate benefits to the players (Palagi 2011). These immediate functions can make applying criterion #2 that "play behavior is incompletely functional in the context expressed," difficult to apply.

Similarly, in some situations, play has been shown to reduce stress. Thus, while severe stress may dampen play, mild to moderate levels of stress may actually facilitate its occurrence (Pellis and Burghardt 2017), making criterion #5, "that play is initiated in healthy, relatively unstressed animals in a relaxed context," difficult to apply in some cases. These limitations are not insurmountable, but to reduce the subjectivity involved in determining how much stress is too much or how small the immediate function needs to be requires more detailed knowledge of the specific case in question. The five criteria are thus a good starting point, but should be applied with the recognition that, to be effective, further research on the behavior and species under investigation may be required to make an objective decision on some of the criteria. Nonetheless, armed with a workable definition, one that can transcend the typically narrow, comparative confines of mammals and a few birds, examination of some of the deeper progress that has been made in the study of play is possible.

## The Many Forms of Play

While in humans play can take many varied forms (Smith 2010), in nonhuman animals three major forms of play are generally recognized (Burghardt 2005). These are locomotor play, involving a lone animal engaging in running, jumping, kicking, and making turns; object play, involving a lone animal engaging in carrying, flinging, ripping, or otherwise manipulating an inanimate object; and social play, involving two or more conspecifics wrestling, chasing, or otherwise manipulating one another. While most cases reported of all these types of play meet the five criteria (Burghardt 2005), there are unresolved issues about the relationship among the types of behaviors encompassed by each kind of play.

When engaged in object play, animals may include a variety of locomotor movements, and social play may involve competition for an object or incorporate locomotor-rotational movements (Burghardt 2005). Consequently, these three types of play may be intermingled in a variety of ways. A further complication is that, often, labeling the three types of play is based on the target of the play (i.e., self, other, object) and not on the actual content of the actions performed, which may be quite varied. For example, the locomotor play of many prey species, such as ungulates, involves the playful execution of the runs, jumps, turns, and other protean movements that are otherwise seen, functionally, in antipredator behavior, whereas, in some species, some of the locomotor behavior may be not only unrelated to antipredator behavior, but are also unique to play, such as the pirouettes done by chimpanzees (Nishida and Inaba 2009). Labeling both as locomotor play may confound behavioral processes that are very different. Conversely, cats may playfully direct predatory behavior patterns to either inanimate objects or to conspecifics. The problem in this case is that even though the same behavior patterns may be used, the differences in target would lead to the behavioral sequences being categorized as different kinds of play. It is not self-evident as to why the behavioral patterns performed have a lower priority in categorizing

play than does the target to which they are directed.

Social play can also be diverse in content. Social interactions involving behavior patterns typical of nurturing young (play mothering), courtship and copulation (sex play), or conspecific aggression (play fighting), have all been categorized as social play (Burghardt 2005; Fagen 1981; Pellis and Pellis 2009). Indeed, even “play fighting” may be an amalgam of behavioral sequences that can involve competitive interactions of diverse origins: the animals may compete for contact with body targets typical of aggression, courtship, greeting, or grooming (Pellis and Pellis 2009).

All this diversity in the content of play raises important questions about both the neurobehavioral mechanisms that produce play and the possible functions that play may serve. One approach has been to view play as being encompassed by a unitary motivational system, whereby behavioral elements from different functional systems can be intermixed (Heymer 1977). Such a view is supported by some studies, convincingly showing that two or more types of play are intermingled, such as object and social play in Japanese macaques (e.g., Shimada 2012). However, contrary to this perspective are accumulating data that suggest that different types of play have different origins and involve different neurobehavioral systems.

First, at a broad phylogenetic level, the three different types of play may appear independently of one another across different lineages (Burghardt 2005). That is, object play can evolve in a lineage independently of either social or locomotor play, and so on. For example, object play is either absent or rudimentary among rodents, whereas locomotor play and social play are quite prevalent. However, even in cases in which locomotor play and the social play are both present and appear to be performed in an intermixed manner, they may not be causally linked. Indeed, when comparing across species, there is a negative correlation between social play and locomotor play – an increase in the complexity of one type of play is accompanied by a decrease in the

complexity of the other (Pellis and Pellis 2009). Such a relationship extends to the subspecies level, with some strains of rats having more locomotor play and some more social play (Schneider et al. 2016). Thus, at a phylogenetic level, different types of play can not only have independent origins, but also follow independent evolutionary changes.

Second, in species which have multiple types of play, different types of play wax and wane at different ages (Burghardt 2005; Pellis and Pellis 2009). That is, the different types of play appear developmentally dissociated. Third, studies of individual differences within species have shown that individuals that exhibit more of one type of play are not more likely to exhibit more of the other types of play (Ahloy Dallaire and Mason 2016; Lampe et al. 2017). Being more playful does not make an individual equally more playful in all ways.

Given that data on phylogenetic trends, developmental changes and individual differences show that different forms of play are independent, how can the cases in which animals seem to intermix behavior patterns from different functional systems be explained? There is an important methodological issue that needs to be resolved before any deeper biological understanding can be gained.

Some reports of mixing are of the following form: a piglet in a crowded pen jumps forward and rotates in the air, striking another piglet on the flank, which leads to a brief tussle between them. Such a sequence has been interpreted as a bout of locomotor play merging into a bout of social play (e.g., Donaldson et al. 2002). That is, locomotor actions are intermixed with socially competitive actions. However, this interpretation may be premature. Consider a young gosling nibbling on grass in a pasture, walking with lowered head while doing so. Periodically, it raises its head and scans its surroundings, and if it has strayed too far from its parents, the gosling will orient and run towards a parent. During this run, the gosling may bump into a sibling, which leads to a brief tussle, before one or both run towards the parents again (Pellis and Pellis 2009). It would seem unlikely that, in such a case, the running and the social

competition resulted from the same motivational substrate. Rather, the most parsimonious explanation would be that the social interaction was an incidental byproduct of one gosling accidentally bumping into another while running towards a parent. Similarly, in animals in close proximity, it cannot be assumed that the running, jumping, and turning are motivated by the same processes that lead to playful competitive interactions when they make contact with a nearby conspecific. Simply scoring the locomotor movements and social actions independently of the context within which they arise can be misleading.

The latter point needs also to be considered when scoring behavior patterns associated with play and then concluding that because some of them occur in functional contexts associated with conspecific aggression and others with anti-predator behavior, sex, etc., that play involves mixing behavior from different functional contexts (Heymer 1977). For example, in grasshopper mice and ground squirrels, play fighting involves two types of competitive interactions – in the mice, they either compete to lick and groom their partner's shoulder area (as in precopulatory behavior) or to bite the nape of their neck (as in predatory behavior), and in ground squirrels, they either compete to mount one another (as in sex) or to bite their partner's shoulder (as in aggression). Individual play bouts last 2–3 s, but over a specific sample period, pairs can engage in dozens of playful interactions. Simply scoring the incidence of mounting, licking and grooming, and biting would suggest that these species mix elements from sexual and aggressive or from sexual and predatory behavior. However, detailed analysis of sequences shows that a play fight that began with a bite directed at the shoulder (squirrels) or to the nape (grasshopper mice) was not countered with counterattacks to lick/groom the shoulder or to mount. Rather, each sequence of attack and defense was appropriate for the target attacked, and only once that sequence was completed would a new sequence start that could involve an attack directed at the opposite target (Pellis and Pellis 2009). That is, at this finer grain time scale, sex and aggression or sex and predation were not mixed.

The conclusion to be drawn is that the apparent intermixing of behavioral elements from multiple functional behavioral systems may be an illusion, and that, in the moment-to-moment context of performing playful actions, behavioral elements from different systems remain distinct. However, there are striking examples of mixing, such as the object-social play of Japanese macaques (Shimada 2012) that cannot be so dismissed. To reconcile such divergent findings, play must be considered with regard to phylogenetic history.

### The Origins and Evolutionary Transformation of Play

Burghardt (2005) developed a model for the independent evolutionary origins and transformation of play across many different lineages of animals that may have important implications for our understanding of both the independence and the combining of types of play. The model asserts that, under certain conditions, such as readily available food, surplus energy, a relatively protected environment, prolonged juvenile development, and with sufficient neural resources to experience boredom, play-like behavior may emerge. This incipient or *primary process play* is the form of play that is most widespread in the animal kingdom, with locomotor, object, or social forms predominating in different lineages (Burghardt 2005). The behavior patterns performed in such play may not differ markedly from their appearance in functional contexts, but the usual functional consequences do not arise. It is possible that under particularly benevolent conditions, such play may be sustained even if it is neutral with regard to fitness benefits (Pellis et al. 2014). An avenue by which such primitive play may begin to gain a fitness advantage has been recently explored in a mathematical model. If the play, at least in its social guise, forces competitors to squander some of their developmental resources, then the cost of inducing that play can be an advantage to the initiator if its cost is smaller than that paid by the competitor (Auerbach et al. 2015).

As noted in the transformational model, if conditions are favorable and primary process play provides players with a fitness enhancing advantage, then the features of the play that are most crucial to that advantage may be subjected to natural selection, so that the critical behavior patterns are either increased in their frequency and/or modified in their form to serve that function better (Burghardt 2005; Pellis et al. 2014). In this way, the play can become even more playful as it is transformed into *secondary process play* and, more strikingly so, as it is further transformed into *tertiary process play*. It should be noted that, in a species with only primary process play, the five criteria in Burghardt's definition of play may only be met to a minimal degree, whereas in a species with secondary or tertiary play, many of the criteria may be fulfilled by a wide margin. This variation, in turn, may account for the marked variation in the complexity of play characterized when researchers contrast cases across a wide comparative range of lineages (Burghardt 2005; Fagen 1981; Pellis and Pellis 2009). The relative fitness gain characterized in the primary process play modeled by Auerbach et al. (2015) also suggests one of the necessary conditions that lead to further transformations of play.

Again, models suggest that once a potential benefit emerges that enhances fitness, play can quickly spread in a population (Durand and Schank 2015). With regard to social play, if playing provides fitness enhancement to one partner at the expense of another, one can imagine a situation arising in which there is a fitness advantage for mechanisms to evolve in competitors to offset that advantage. That is, a kind of arms race develops, with a momentary advantage gained by partners initiating play being neutralized by new actions by the recipients, leading to ever greater levels of complexity in the play performed (Pellis and Pellis 2016). The broad outline of such a transformational process has been characterized for the play of murid (i.e., mouse-like) rodents (Pellis and Pellis 2009; Pellis et al. 2014).

In murid rodents, social play in the form of play fighting involves attack and defense of body targets otherwise contacted during adult pre-copulatory behavior, and across species, this

competition can differ markedly in its complexity. At the simplest levels, there are species that do not engage in any such play and some that attack but do not defend. At a more complex level, defense occurs, but that defense involves evading contact, not wrestling. The addition of tactics that promote the occurrence of playful wrestling makes play even more complex. Finally, high frequencies of counterattack lead to even more complex play fighting, as partners can reverse roles over the course of the encounter. For example, in Fig. 1, play fighting in a pair of juvenile rats is shown, in which attack, defense, and counterattack lead to a

protracted interaction involving close-quarter bodily contact.

From a mechanistic perspective, the greater complexity in the form of the play is accompanied by changes in the neural mechanisms that regulate play (Pellis and Pellis 2009). In the case of murid rodents, these changes in neural organization gradually lead to more and more differentiation from the sexual behavior being performed during play. Other than the precocial expression of emerging behavior patterns, there is little evidence that the simplest forms of play require novel mechanisms to sustain it. In contrast, more

**Play Behavior, Fig. 1** A sequence of play fighting is shown for a pair of juvenile rats. The rat on the left approaches another rat from the rear (a) and pounces towards its partner's nape (b). Before contact is made, the defender rotates around its longitudinal axis (c) to face its attacker (d), but the attacker continues to move forward pushing the defender onto its side (e). The defender then rolls over onto its back as its attacker stands over it, restraining the defender's movements while continuing to reach for its nape (f–h). The supine defender launches a counterattack to its partner's nape (i), which is blocked (j, k). With continued squirming by the supine partner, the rat on top (l) is pushed off by the supine animal (m). The original defender then stands up (n) and lunges towards its partner's nape (o). The sequence involves repeated attack and defense of the nape and role reversals to which partner attacks and which defends (Reprinted from Pellis and Pellis (1987) with permission)

complex forms of play require changes to the regulatory mechanisms that produce sex-related behavior. The most complex forms require novel involvement of cortical systems (Pellis and Pellis 2016). From a functional perspective, there is little evidence for the fitness enhancing effects of the simplest forms of play, but more complex ones appear to have detectable effects on the development of sexual performance and for the most complex ones, additional benefits for the development of more general cognitive and social skills (Pellis et al. 2014).

The transformation of play across lineages and the unique attributes afforded by different lineages begins to provide a solution to the conundrum of different forms of play having originated independently, but clearly, in some species, intermixed in novel ways. First, a lineage must have evolved more than one type of play to afford the opportunity of intermixing behavior from different types of play (Burghardt 2005). Second, the lineage in question must have the resources to combine these different elements effectively when the opportunity presents itself. For example, as noted above, the two most common and elaborate forms of play in rodents – social and locomotor play – are negatively correlated (Pellis and Pellis 2009). That is, increased complexity in one is coupled with a decreased complexity in the other, suggesting that there may be limited neural resources available to allow for the expansion of both types of play. It may, therefore, not be surprising to discover that some of the most convincing cases of intermixing are to be found in primates (e.g., Shimada 2012) – a lineage with a larger brain to body ratio than that in rodents (Eisenberg 1981).

As noted above, while insufficiently fine-scale temporal and contextual analyses may account for many of the presumed reports of intermixing during play, some cases may be true reflections of the composite play possible in some species (Palagi and Norscia 2016). The above transformational model offers a means by which to account for the species differences that may underlie some of this variation in being able to intermix behavioral elements from the different functional systems being mimicked during play. At least one of the

crucial resources needed to make the transition from maintaining independent play systems to novel combinations of such systems is to have a sufficiently large brain. A potential way that such neural resources could make the difference is reflected in the brain-level changes needed to make social play more complex (Pellis and Pellis 2016).

## The Playful Brain

In rats, play has been shown to engage a complex neural circuit of interconnected systems (Siviy 2016). Thus, there are hindbrain systems that generate the appropriate behavior patterns, midbrain systems that motivate and reward the execution of play, lower forebrain systems that regulate the emotions involved and upper forebrain systems that modulate the actions performed to ensure that they are contextually appropriate.

Intriguingly, rats that have had their cortex removed at birth exhibit normal levels of play in the juvenile period, with similar frequencies of attack, defense and counterattack, and exhibit similar levels of reciprocation in their play (Pellis and Pellis 2016). That is, neural circuits below the level of the cortex are sufficient to motivate and execute play and provide the reward necessary to sustain it. This is consistent with the likelihood that the changes needed to transform primary process play into secondary process play in rodents have involved alterations to subcortical circuits (Pellis and Pellis 2009). While not needed to produce or maintain play, cortical circuits, especially those of the prefrontal cortex, are critically involved in modifying the play executed to adapt it, contextually, to both the identity and the actions of the partner (Pellis and Pellis 2016). That is, transforming play from secondary process play to tertiary process play requires higher levels of neural control over the mechanisms regulating it, to make play more complex and adaptable to novel contexts.

Viewed from the knowledge gained thus far about the neural mechanisms involved in producing, maintaining and adaptively modifying social play in rats, a possible way for more complex play

to evolve is for there to be more neural resources engaged, especially by adding more control from neural circuits higher up in the neural hierarchy. Comparatively, even among murid rodents, only

some species have achieved the levels of complexity in social play present in rats, and these have emerged seemingly independently (Fig. 2). These findings lead to two considerations.

**Play Behavior, Fig. 2** The evolution of complexity in play fighting is shown for several species of murid rodents. The species are mapped onto a cladogram, a tree-like diagram that shows the pattern of relatedness among the species, with those sharing a closer node being more closely related than to those from nodes further away. For example, *Rattus* and *Mus* are more closely related to one another than to *Notomys*, but they are both more closely related to *Notomys* than they are to *Mesocricetus*. The insert represents play complexity with the score of 0 indicating little or no play and a score of 4 indicating very complex play. The base of the tree shows that the ancestral state was one of moderate complexity. The species on the terminal branches independently either increased or

decreased the complexity of their play. Note that for most species, only the genus is shown, as only one species is represented for that genus. In the case of voles (*Microtus*), more than one species of the same genus are shown (*M. agrestis* = European vole; *M. ochrogaster* = prairie vole; *M. montanus* = montane vole). For the other genera, *Rattus* represents the Norway rat, *Mus* the house mouse, *Notomys* and *Psuedomys* represent two species of hopping mice, *Mesocricetus* represents the Syrian golden hamster, *Phodopus* the Djungarian hamster, *Onychomys* the Northern grasshopper mouse, *Peromyscus* the deer mouse, *Meriones* the Mongolian gerbil and *Psammomys* the fat sand jird (Reprinted from Whishaw et al. (2001) with permission)

First, while some species of rodents do not play at all and many of those that do have relatively simple forms (Pellis and Pellis 2009), in some other lineages, especially primates, there is not a single species of which we are aware that does not play, with that play probably being at least as complex as that present in rats (Fagen 1981; Palagi and Norscia 2016). That is, lineages with more neural capacity available may be more likely to spawn species with complex play (Pellis and Pellis 2009). Second, the sporadic nature of evolving more complex patterns of play in rodents (Fig. 2) suggests that factors other than increased brain size, such as favorable energy budgets and social systems, may be needed to promote the further evolution of playful complexity (Burghardt 2005). These considerations have a direct impact on why some species may be able to intermix different behavioral elements in their play.

Lineages such as primates, which have, as a group, above average brain size (Eisenberg 1981), have the neural capacity to produce moderate to highly complex play of more than one kind. All species observed have been reported to exhibit complex social play (Fagen 1981; Palagi and Norscia 2016). In addition, some species are noted for their complex locomotor play (e.g., Nishida and Inaba 2009), and others for their complex object play (e.g., Nahallage et al. 2016). Thus, species with the neural resources to evolve complex play of different types, under the right conditions, may also have the incentive, and the requisite level of neural control over play, to be able to intermix behavioral elements from different types of play into novel combinations. If

this model is correct, then the intermixing of behavioral elements in play is not as previously thought, a key characteristic of play (Heymer 1977), but rather, is an evolved feature that arises in the play of particular lineages. At present, there are some major holes in our knowledge that do not make a full evaluation of this model, or any alternative models, possible.

The biggest problem is that the only species for which knowledge of the neural circuitry involved in play is reasonably well developed is for the laboratory rat. In rats, while some play involves locomotor play, the vast majority involves social play, in the form of play fighting (Pellis and Pellis 2009). Consequently, discussions focused on the ‘mammalian play circuit’ (Siviy 2016) are really about the social play circuit of rats. Knowledge of the neural underpinnings of locomotor play and object play is exceedingly sparse. What does seem likely is that all forms of play are likely to tap into the brain’s reward mechanisms, but such a connection is true for most motivated behavior (Berridge and Kringelbach 2013), and so, in itself, is not especially revealing about how different forms of play connect to one another at a neural level. Moreover, as a comparative overview of play reveals, what is labeled as play may have many different grades of complexity (Burghardt 2005; Pellis et al. 2014).

Therefore, if species as model systems are to be selected, they need to be selected within a matrix that compares species with only one type of play and those with multiple types of play in their repertoire on one axis, and the degree of transformation (primary process play, secondary process play, tertiary process play) on the other (Table 1).

**Play Behavior, Table 1** The complexity and evolutionary transformations across different types of play can be mapped in a two-dimensional space, accommodating a wide range of species

| Type/complexity <sup>a</sup> | Absent          | Primary process | Secondary process | Tertiary process |
|------------------------------|-----------------|-----------------|-------------------|------------------|
| <b>Object</b>                |                 | SH, NR, HM, MG  |                   |                  |
| <b>Locomotor</b>             | SH <sup>b</sup> |                 | MG                | NR, HM           |
| <b>Social</b>                |                 | HM              | MG                | SH, NR           |

<sup>a</sup>Play can be either absent, or, if present, can be of varying degrees of complexity using the framework from Burghardt (2005)

<sup>b</sup>Abbreviations represent different species of murid rodents: *SH* Syrian golden hamster, *NR* Norway rat, *HM* house mouse, *MG* Mongolian gerbil. For sources on the primary data on the play of these species, see Pellis and Pellis (2009)

For example, of the four species of murid rodents entered in Table 1 for illustrative purposes, all have, at best, primary process play for object play, but a more diverse distribution for the other two types of play. One has very complex social play (e.g., Syrian golden hamsters) and one has very complex locomotor play (e.g., house mice), and another has social play and locomotor play that are both of moderate complexity. Only in rats does locomotor play involve hops, jumps, rotations, and runs that match that of house mice in complexity (tertiary process play) and have prolonged wrestling in their social play (see Fig. 1) that matches Syrian golden hamsters in complexity (tertiary process play).

While it is unknown whether the neural components involved in social play in rats (Siviy 2016) are the same as those involved in locomotor and object play, there is some degree of confidence that at least the major components of the social play circuit characterized in rats may also be active in the social play of other lineages, such as primates (Graham 2017). For the other dimension, that of level of transformation, if the picture for social play derived from rodents is reflective of the processes involved in other lineages and other forms of play, then it would be predicted that as any type of play increases in complexity, the level of control by cortical circuits would also increase. Therefore, cases of true intermixing of types of play would be expected to be limited to those species that have achieved tertiary process play in two or more kinds of play. For example, in rats, in which both social and locomotor play are very complex (Table 1), hops and other locomotor movements seen in solitary locomotor play are incorporated into their social play, suggesting a degree of intermixing of different types of play that is not present when one or more of the types of play present are at a lower grade of organization (Pellis and Pellis 2009). Much comparative neuroscience remains to be done.

## The Functions of Play

The comparative literature has traditionally been focused on identifying the functions of play

(Martin and Caro 1985). Recent studies with free-living populations of several species have revealed that functionally beneficial outcomes of play are present in some species, but not all (Pellis and Burghardt 2017). In part, these mixed results may arise because of the comparative diversity in both the kinds of play that predominate and the level of complexity that such play may have across the species used for such tests. For example, a common function proposed for play fighting is that it provides training for combat skills (e.g., Fagen 1981). However, play fighting involving competition for an advantageous position typical of sex, as seen in rats or squirrels, may be a poor avenue for training combat skills (Pellis and Pellis 2009).

Furthermore, for play fighting to remain playful, the partners need to curtail their combat to some degree to allow for whatever minimum level of reciprocity is required for the species in question and this may attenuate the fitness benefits derived from the practice afforded. The level of reciprocity varies with species, with age, sex, and dominance relationships, but play cannot be sustained if contests are completely one-sided – in situations in which one individual attempts to dominate the play completely, its partner will refrain from playing further with that individual. Adhering to a mutually agreed level of reciprocity is needed to make play fighting “fair” and so induce the players to keep playing together (Palagi et al. 2016). Different lineages have evolved different rules for ensuring reciprocal exchanges during play fighting. In some, the combat actions themselves are executed in a restrained manner, whereas in others, the restraint is interjected once a combat tactic is used to gain the upper hand. Unlike the former species, in the latter ones, the combat tactics are executed in a way that is seemingly identical to how they are used in serious fighting (Pellis and Pellis 2009). For such species, play fighting may provide an avenue for training combat skills.

These examples illustrate that species differences in how particular kinds of play are performed can greatly influence the development of particular skills. In the above case, a researcher selecting one species may find that there is a

strong correlation between juvenile play fighting and adult fighting skills, whereas another researcher using a different species may find a weak or absent correlation. The situation becomes even more complicated when both type of play and species differ. For example, during the juvenile period, the predominantly social play of rats is executed in such a manner that they experience many instances in which they lose and then regain control over their own bodies and over the movements of their partners (Pellis and Pellis 2009). The executive functions of the prefrontal cortex, such as those involving attention, short-term memory, emotional regulation, and decision making, are improved if rats engage in play with peers as juveniles (Pellis et al. 2014; Vanderschuren and Trezza 2014). That is, the play of rats has the effect of training them to be more resilient (Pellis and Pellis 2009). In contrast, in the house mouse, those individuals that play more appear to be less resilient as adults than those that play less (Richter et al. 2016). But there are two major differences to be considered: first, mice and rats may differ in the complexity of their neural control mechanisms, and second, in mice, unlike rats, the predominant form of play is locomotor play (Pellis and Pellis 2009). That is, the difference between the two species in the relationship between play and resiliency does not negate one another, as different forms of play may differ in their beneficial influences on development. Thus, while locomotor play may improve motor skills in some species, that species may not have the resources to improve executive functions with such play.

Another dimension to consider about the functions of play is whether the play has immediate or delayed benefits. In most examples for which benefits have been demonstrated, it has been for play in the juvenile period having beneficial consequences later in life, but in some cases, play appears to increase survival at that age in which it is performed (Pellis and Burghardt 2017). As already noted, the play of an adult with another adult likely only serves immediate benefits, not delayed ones (Palagi 2011; Pellis and Pellis 2009). It is this complex blend of the types of play present, the complexity

of the play, the species involved, and the age of the players, which makes any test of a functional hypothesis likely to fail. Selecting the most appropriate species for the functional hypothesis to be tested may require consulting a matrix like that in Table 1, in which species with particular types of play and play complexity can be identified. As for understanding the neurobehavioral mechanism of play, much more comparative work needs to be done before functions widely associated with play and those idiosyncratic to particular forms of play in particular species can be identified.

## Conclusions

Even a casual reading of the above review will quickly reveal a major element that is missing in the story – most of the examples, and all those involving detailed analyses of behavioral content, neurobiology, and functional consequences involve mammals. What about all the other species and lineages that have been reported to meet the five point criteria in Burghardt's definition of play? Where do nonmammalian vertebrates fit in, much less the myriad invertebrates that play? We have deliberately focused our review on mammals to show that even within the taxon that has been most intensively studied with regard to play, there are some major gaps in our knowledge. By understanding the problems that need to be resolved so as to have a comprehensive theory of the mechanisms and functions of play in mammals, the difficulties in integrating a broader swathe of species from diverse lineages can be placed in context. Some studies of birds suggest that some of the same considerations outlined above also apply to this lineage. For example, increased brain size in birds increases the likelihood of play, but likely does so as it may in mammals, by lengthening the juvenile period and thus increasing the opportunity to play. Similarly, the complexity of social play can vary in birds in ways similar to that outlined above for mammals (Pellis and Pellis 2009). Further afield, only sporadic examples are available for reptiles, fish, and other nonmammalian/nonavian

vertebrates (Burghardt 2005). The breadth of species becomes even more impoverished as examples are sought among invertebrates (Burghardt 2005; Pellis and Burghardt 2017). At present, the lack of breadth in the literature on the distribution of types and complexity of play makes the development of a comprehensive theory that encompasses the whole animal kingdom highly elusive.

For example, in mammals, play is predominantly a phenomenon of the juvenile period (Fagen 1981), with some forms of play being retained in adults in some species (Palagi 2011; Nahallage et al. 2016). This requires an emphasis on the kinds of factors that have promoted play to emerge in the juvenile period of some species but not others (Burghardt 2005), and an understanding of the factors that have led to play in some of these species being retained in adulthood (Pellis and Pellis 2009). However, several species of cephalopods have been identified to engage in play with objects (Burghardt 2005), but all these octopuses are adults. To our knowledge, no one has reported play in the young of these species. This is perhaps understandable in that most of these species have planktonic young, thus being much smaller and of a different body shape to the adults, so likely do not have the neural wherewithal, the body morphology or the favorable ecological conditions that make play possible. Thus, in contrast to mammals, in cephalopods, play is a phenomenon of adulthood. Such contrasting aspects of behavioral phenomena that meet the conditions set by Burghardt's five criteria have to be taken seriously in developing general theories of play. Clearly, a first step in such an endeavor is to describe the types and complexity of play across a wider range of species from across many different taxa.

## Pleiotropy

Melissa Postal

Instituto Federal de Educação, Ciência e Tecnologia Farroupilha, Panambi, Brazil

Pleiotropy is the term used to describe the phenomenon where a single mutation affects more than one phenotypic characteristic of the organism (Stearns 2010). Pleiotropy can occur at the allelic level, where a single causal variant is related to multiple phenotypes, or at the gene (or region) level, at which multiple variants in the same gene (or region) are associated with different phenotypes (Solovieff et al. 2013). The term was defined in 1910 by the geneticist Ludwig Plate (Stearns 2010); this trait has implications for genetics, evolution, development, age, disease, and discovery of new drugs (He and Zhang 2006). Before that, in 1866, Mendel reported this type of genetic inheritance in his study with *Pisum* species: he attributed three characteristics (seed coat color, flower color, and axial spots) to a single factor. Although this explanation is not confirmed, it denotes the significance of this mechanism. Many studies have been conducted in different areas of biology using pleiotropy as a target or basis for research. Between them, evolutionary dynamics are influenced by pleiotropic mechanisms in different ways: a single gene product with multiple effects will be strengthened or weakened by processes different from those that will impact a single gene that can produce multiple products. Multiple reading frames and alternative transcripts may be more difficult for evolution to disrupt than a single product incorporated into different pathways (Stearns 2010). According to Reusch and Wood (2007), the effects of pleiotropy on adaptation are important: when they act synergistically, they could allow the population to quickly produce new solutions to environmental problems. An example known as pleiotropy antagonist also operates in evolutionary processes: this phenomenon can be explained by variants that exert different functions according to the period of life, for example,

## Playing Possum

### ► Tonic Immobility

genetic variants that exert beneficial effects in the early stages of life may turn out to be detrimental at older ages and vice versa (Giuliani et al. 2017). Pleiotropy can be caused by a single locus with multiple primary products or by a single product originated from a gene that is incorporated in several different ways (He and Zhang 2006). From this perspective, three categories of pleiotropy can be described: biological pleiotropy where causal variants of different traits fall into the same gene or regulatory unit (e.g., transcription factor binding sites) (Solovieff et al. 2013); mediated pleiotropy refers to the case where a variant directly affects one trait, which in turn affects another (Hackinger and Zeggini 2017); spurious pleiotropy involved encompasses various sources of bias that cause a genetic variant falsely to appear to be associated with multiple phenotypes (Solovieff et al. 2013). In a study of yeast pleiotropic genes, He and Zhang (2006) concluded that “gene pleiotropy is generally achieved by the use of a single molecular function in multiple biological processes, which is realized in part by the distribution of the gene product into multiple cellular components and by participation of the gene in different protein–protein interactions.” Many studies are still being carried out about pleiotropy, demonstrating the importance of this process for several areas of biology and proving that it is more than “artifacts” or “misinterpretations” in genetic research.

## Definition

A point light display is an experimental paradigm. Instead of presenting the moving body, it only displays the movements of a few landmarks on the body, typically as white points against a dark background.

## Introduction

Point light displays, usually referred to as “point light biological motion” or simply “biological motion” (see also the chapter on ► [“Biological Motion”](#)), have enjoyed a rich research tradition since the 1970s and have been widely applied. Fields of application involve experimental psychology, cognitive development, ► [primate cognition](#), neurology, pain research, and action perception. Using point light displays in research studies is attractive, first because they are easy to generate and manipulate computationally and, second, because they allow the study of the ► [visual perception](#) of biological movement without the rich visual context that is typical of movies.

## History

The point light display was developed by the Swedish Gestalt psychologist Gunnar Johansson, who also coined the term *biological motion* (Johansson 1973). Although the term biological motion is reasonable for visual scientists, it is a misnomer from the biological perspective, because biological motion refers to the movements of biological organisms, rather than just the abstracted visual presentation thereof.

At the time Johansson had formulated Gestalt laws for movements. Gestalt laws are generalized rules for how the visual system structures and organizes the chaotic visual scenes that fall on the retinas. Applied to short sequences of a few moving dots, he found, for example, that observers can recognize a rolling wheel (i.e., the sum of the principles of rotation and translation) from the movements of just two points. When searching for a more complex stimulus to test his

laws, Johansson was completely stunned by the robustness and vividness of the point light display of biological motion. These findings inspired hundreds of scientific studies.

## Technique and Stimulus Types

Originally, an actor dressed in black with bright dots stuck to some major landmarks of the body was filmed against a black background, so just the moving “point lights” showed the movements of the – otherwise invisible – body.

Soon, a simple software program for computing an artificial point light stimulus, simulating a “person walking in-place,” was published (Cutting 1978). Although the resemblance to real walking is really quite superficial, human subjects readily identify this artificial stimulus as a walking person. This feature, and the ease with which this stimulus can be implemented, rapidly popularized the use of point light displays in visual research.

Three-dimensional (3D) kinematic recording techniques and reflective markers attached to whole-body morph suits combined with computer processing power have now replaced the original video technique. Various databases of such recordings are freely available.

Many experimental paradigms have been published, such as visual detection tasks, choice tasks, priming, and so on. Typically, a fixation point is used to control the eye movements. The retinas of primates (and many other animals) have a fovea, a small central field in which vision is greatly enhanced with respect to the visual periphery. Therefore, to control which information exactly enters the brain, it is essential to either keep the eyes fixated or measure the movements of the eyes.

Various paradigms have used masks. Such a (invisible) mask may obscure parts of the stimulus, or it may consist of a large number of moving point lights of the same size and color as the stimulus' point lights.

Point light displays have usually been presented as white points moving on a dark background, but isoluminant points and points of a limited lifetime have been used as well.

Isoluminant stimuli differ from the background by color, but not by brightness. In such stimuli, the points are as bright to the eye as their surroundings. Points of limited lifetime are present only for some time before reappearing on a different location of the body. In the extreme case, the points are presented on one location of the body for just a single display frame. In such a “single frame lifetime” (SFL) display, the observer sees much flicker, but no movement in the direction of the actor’s motion.

Finally, the point lights may have the shape of objects, such as small fruits or tools or even small point light displays.

## Paradigms and Findings

Early studies focused on the robustness of the percept, for example, by embedding the point light movements in a dense field of distracting points. These studies demonstrated the immense ability of the visual processing system for perceptual grouping of biological motion within point light displays. Even if parts of biological motion stimuli are covered or if the point lights are displayed among a large number of distracting point lights, humans can easily recognize the stimulus visually.

Various studies have been performed to establish the richness of information that observers obtain from point light displays. Biological motion conveys rich information to the observer. For example, humans can perceive the gender, weight, and mood from the mere point movements and can reliably identify friends as well as themselves. On the other hand, humans are very tolerant to errors in the stimulus. For example, observers do not notice if the stimulus misses hands and feet. Naive observers readily accept even an artificial stimulus of pendular sine and cosine movements as human walking (see above: Cutting 1978).

The recognition of point light biological motion has been shown to be size-invariant, but not orientation- or location-invariant. That means that human subjects can easily perceive and can even perform decision tasks on point light

displays whose size changes randomly from image frame to image frame.

Counterintuitively, it has been found that point light biological motion is easily recognized even if nothing moves in the display. This has been shown with the SFL display, in which there is a lot of flicker, but no systematic movements of the point lights. On the other hand, biological motion is difficult to recognize if the point lights are replaced by objects (such as tools or fruit). These findings indicate that the visual perception of point light displays is similar to object perception, rather than motion perception.

Other paradigms have used point light biological motion displays to study perceptual effects such as depth perception, biases, bistability, and so on. Since the point lights move in the 2D display, the stimulus conveys ambiguous depth information (Video 1). It is thus impossible to tell if the presented person faces out from the display or into it. However, observers will more frequently report that the presented actor is facing out of the display. This so-called facing the viewer bias has received considerable medial attention. It was thought at first to have an evolutionary origin but in the end turned out to be mainly caused by a geometric perceptual bias for relative point motion.

Further, when looking at it for some time, the two possible percepts will spontaneously alternate. This effect is known as a so-called bistable percept.

## Applications in Animal Research, Patients, and Infants

A number of studies have been performed with rhesus macaques and pigeons as subjects. These have shown that primates and birds perceive biological motion from point light displays. Pigeons may show courtship behavior when presented a point light display of a female pigeon (Troje and Aust 2013). Electrophysiology (electric recording from electrodes stuck into the cortex) in macaques identified neurons in the ► [superior temporal sulcus](#) (STS) that respond to point light displays of biological motion, but not to random

point light displays (Oram and Perrett 1994). This finding has been well established for biological motion. Even neurons in the monkeys' premotor cortex are now known to respond to visually presented actions (Gallese et al. 1996).

Newborns show a clear preference to look at point light displays of biological motion rather than other point light movements (Fox and McDaniel 1982).

A number of studies have investigated patients, suffering, for example, from schizophrenia, autism, and various brain lesions. Some very rare lesion patterns may make a person unable to see motion, whereas they are able to identify visually presented objects. Such patients who are called motion agnosia, were found to perceive point light biological motion displays (Vaina et al. 1990).

## Theory and Modeling

From the beginning, theories and models for the perception of biological motion have focused on mechanisms for visual motion perception. However, many findings indicate that the recognition of biological motion stimuli is driven primarily by the same perceptual mechanisms that underlie the visual perception of objects. As mentioned, motion agnostic patients are not impaired, and healthy persons easily identify SFL displays as biological motion. On the other hand, individuals with facial agnosia (more widely known as prosopagnosia, for severe problems with recognizing faces) are also impaired in recognizing biological motion. Lastly, biological motion is masked effectively if the points are displayed as objects (see above).

A recent theory for biological motion recognition solely depends on visual mechanisms for object recognition (Theusner et al. 2014). The model in addition proposed that the sequential order of recognized body postures is aligned in the brain to more easily recognize the displayed action. The perception of such sequences of configurations is known as higher-order motion detectors, or motion-from-form detectors, and is thought to occur in the ► [superior temporal sulcus](#) (Oram and Perrett 1994; Barraclough et al. 2006).

On the basis of the nineteenth-century theorizing by the pioneer of psychology, William James, it had long been predicted that the motor systems in the brain also play an important role in the understanding of actions. By coincidence such neurons were found in the macaque premotor cortex, which responded only if the monkey performed a specific movement (e.g., a precision grip) but also if the monkey saw another person perform the same specific action (Gallese et al. 1996). This role of the motor system for visual perception of actions is now widely accepted (Rizzolatti and Craighero 2004) and has found various applications with point light displays.

## Conclusion

Point light displays of biological motion have enjoyed a rich and wide field of applications in visual sciences, for humans, monkeys, and pigeons. The stimulus has greatly added to the understanding of visual processes. By virtue of the theoretical framework, the displays have even found their way to neurological applications related to sensorimotor control and action understanding.

## Introduction

An early developmental hallmark in human social cognition is the ability to understand pointing as a form of referential communication. Referential pointing in humans is a triadic communicative transaction involving the management of joint

attention between an informant, a receiver, and a subject of interest. Pointing is not only adaptive as a form of communication but it can also inform a receiver and an informant about each other’s visual perception, social awareness, and knowledge state. In human infants, the ability to understand the referring function of the pointing cue develops over the first 2 years of life (reviewed in Pfandler et al. 2013). Since the early 1990s, there has been an “explosion” of studies in non-human animals on how they respond to pointing cues, whether they produce pointing cues, and if they appreciate a pointing cues’ referring function (see summaries in Miklosi and Soproni 2006, Pack and Herman 2006; Lyn 2010; Kaminski and Nitzschner 2013; Halina et al. 2018). This entry summarizes key findings on these topics and discusses proposed mechanisms, including domestication, through which some species may have acquired an ability to understand pointing.

## A Classic Approach Used to Investigate Pointing Comprehension in Animals

The “object-choice” task is often used to study pointing comprehension. An informant points at whichever of several containers was previously baited, and the receiver must use the informant’s cue to find the bait. Occasionally, arbitrary objects instead of containers are employed, and the receiver is rewarded for carrying out the informant’s designated action to the indicated object. In both approaches, an animal’s *immediate* success when confronted with novel variations in the type of pointing cue (e.g., “direct pointing” – using the arm ipsilateral to the target or “cross-body pointing” – using the arm contralateral to the target) (see Fig. 1), the spatial relationship between the cue and the target (e.g., proximal or distal), the location of the informant (e.g., equidistant between the objects or asymmetric – either closer to the target or nontarget), temporal aspects of the cue (e.g., “static” – in place already when the receiver views it, or “dynamic” – presented and sustained in view of the receiver, or “momentary” – presented for one or several seconds), the number of objects and their

**Pointing, Fig. 1** Artist's (J. Napurano) rendering of different pointing cues. *DP* direct pointing (pointing with the extended whole arm, hand, and finger on the ipsilateral side of the target), *LCP* long cross-body pointing (pointing with the extended whole arm, hand, and finger on the contralateral side of the target), *ECP* elbow cross-body pointing (pointing with the contralateral arm with the pointing finger kept inside the body silhouette and elbow protruding on the side of the nontarget), *SCP* short cross-body pointing (same as *ECP* except elbow tucked into side of

informant's body), *FCP* forward cross-body pointing (pointing using the contralateral extended whole arm, with hand and finger kept within the body silhouette), *EP* elbow pointing version 1 (pointing using the ipsilateral elbow with fist at shoulder), *EP2* elbow pointing version 2 (pointing using the ipsilateral elbow with fist at waist), *LP* leg pointing (pointing using the extended ipsilateral leg and foot), *CLP* cross leg pointing (pointing using the extended contralateral leg and foot), *KP* knee pointing (pointing using the ipsilateral knee)

arrangement, and any additional cues accompanying pointing (e.g., gazing at the target, hereafter referred to as "target gazing" or gazing at the subject, hereafter referred to as "subject gazing" or gaze alternation between the subject and target) can help reveal how pointing is understood. For

example, pointing comprehension that is limited to conditions in which an informant's pointing finger is either touching or very close to the target may be explained in terms of stimulus or local enhancement (i.e., the pointing cue attracts the receiver to the target or an area where it

encounters the target). Likewise, pointing comprehension with distal objects that is limited to direct dynamic pointing may be influenced by an enhancement-like process inasmuch as the sustained cue provides an asymmetric body image that not only can attract a receiver to a particular area where its chances of encountering the target are increased but also provides a stimulus that the receiver can repeatedly check back against as it moves in the direction of the target.

To guard against such noncommunicative uses of pointing, studies have employed momentary direct pointing and cross-body pointing to distal objects, as well as asymmetric pointing in which the informant's pointing finger is physically closer to the nontarget. In addition, static pointing (described above) and reverse pointing (in which the static pointing arm is lowered in the opposite direction) are useful in revealing if responses are contingent on a receiver perceiving movement in particular direction. Finally, a receiver's accurate responses to an informant's points in novel contexts such as to objects out of its immediate view, to objects aligned with each other on the same side of the informant, and to objects requiring attention but not direct action can collectively provide evidence that the receiver understands the referring function of the pointing cue. Across all of these manipulations, accurate performance on initial trials is essential for eliminating associative learning as an explanation of a receiver's responses to pointing. Below, representative studies of pointing grouped by animal type are presented and assessed for what they reveal about a subject's understanding of the communicative function of the pointing gesture. Unless otherwise specified, an informant's extended index finger aligned with the indicated object and accompanied by variations in the positioning of the arm and hand of the pointing finger constituted the pointing cue. Distances between the informant's pointing finger and the target were considered proximal when  $\leq 40$  cm and distal when  $\geq 50$  cm (see Miklosi and Soproni 2006). Statistically significant performances above what would be expected by chance are referred to as "above chance."

## Pointing Comprehension in Object-Choice Tasks in Human Infants

As noted by Pfandler et al. (2013), many early studies of pointing comprehension in human infants examined the orientation responses of an infant to its mother's pointing cues while seated on her lap. In contrast, most studies with nonhumans employ object-choice tasks in which, after experiencing an informant's pointing cue, the receiver is free to move towards and physically select one of several alternatives. Because the latter method may be more representative of the natural way communicative pointing is achieved, and for comparative purposes, recent studies of human infant pointing comprehension have also employed object choice tasks. For example, some 12-month-olds in an object-choice task understand a dynamic cross-body pointing cue accompanied by dynamic gazing or gaze alternation, and those that can also able to reverse roles (i.e. they can also produce these cues) (Behne et al. 2012). By 18 months, infants can use an informant's dynamic pointing cue alone to find a container positioned  $\leq 60$  cm from the pointing finger (Itakura and Tanaka 1998), and by 24 months, they can understand an informant's static direct and cross-body asymmetric pointing cues to more distally placed objects (Povinelli et al. 1997). To better understand the development of pointing comprehension, Pfandler et al. (2013) investigated how 16 infants responded to pointing at 12, 14, 16, and 18 months of age. On each trial, an informant produced one of the following momentary distal pointing cues: direct pointing, long cross-body pointing, forward cross-body pointing, and far direct pointing (Fig. 1). As infants aged, they responded more accurately to pointing cues. Although a few individually performed well with pointing cues at 12 and 14 months, at the group level, infants performed poorly. For example, in response to far direct pointing, most infants at 12 months tended to select the closer nonindicated object. In contrast, starting at 16 months, a significant number of infants performed above chance on first trials with distal direct pointing, long cross-body pointing, and forward cross-body pointing, and

by 18 months, most infants understood the far pointing cue.

## Domesticated Animals

### Dogs and Cats

Initial studies of pointing comprehension in dogs established their ability to exploit dynamic or momentary pointing cues to distal objects including those out of direct view (reviewed in Miklósi and Soproni 2006). For example, Hare et al. (1998) tested how two dogs (one experienced with human pointing in the context of retrieving distally located objects and the second with no previous human pointing training) responded to human direct dynamic pointing with gaze alternation to whichever of two or three containers placed in front of or behind a dog was baited. Each dog performed above chance in all conditions. In follow-up tests involving static pointing, both dogs performed above chance, one immediately. Next, Hare et al. (1998) used dynamic long cross-body pointing and dynamic “belly” pointing (i.e., elbow cross-body pointing) (Fig. 1), with the informant positioned between two containers as well as behind the unbaited container. Both dogs performed above chance with long cross-body pointing when the informant was positioned between the containers, but only one was correct when the informant pointed distantly to the baited container from behind the unbaited container. Neither dog responded accurately to elbow cross-body pointing from either of these positions.

In another early study, Miklósi et al. (1998) tested 11 family-raised dogs, some of which were highly trained assistant dogs, for their responses to momentary distal pointing cues. Collapsing the data across two tests, 10 of 11 dogs responded above chance to whichever of two containers was indicated by an informant. An analysis of responses across trials revealed that associative learning was not a factor in their performance.

Soproni et al. (2002) expanded on these investigations by examining a dog’s ability to understand different forms of pointing. Of

nine dogs tested, between two and seven performed above chance with momentary direct pointing, reverse pointing, direct pointing using a stick, far pointing, long cross-body pointing, and elbow pointing (Fig. 1), with no evidence that the dogs learned how to perform across trials. Thus, dogs showed good generalization to different forms of pointing including those in which movement was in the opposite direction as the target. Also, as in Hare et al. (1998), the results suggested that the side of the informant’s body on which the arm protruded largely governed the object to which responses were made. That is, when the pointing finger was kept within the informant’s body frame and an elbow protruded on the side of the unbaited container (i.e., elbow cross-body pointing), dogs seemed confused, and in the case of asymmetric elbow cross-body pointing, selected the unbaited container leading to significantly below chance performance. In contrast, when the pointing finger protruded from the side of the informant positioned at the unbaited container (i.e., far pointing), dogs were more successful. In a follow-up study, Lakatos et al. (2009) confirmed the ease of dogs with distal direct and long cross-body pointing cues, as well as their difficulty when an informant’s pointing gesture was kept within their body’s silhouette as occurs in elbow cross-body pointing and forward cross-body pointing. Lakatos et al. (2009) found that comprehension of elbow cross-body pointing was also difficult for 2-year-old children, although by 3 years, they had no difficulty interpreting this cue.

To better understand if dogs understand the referring function of pointing, Lakatos et al. (2012) examined their ability to follow its geometry by arranging two bowls in line with each other on each side of an informant who used a direct momentary pointing cue to indicate the baited bowl. Thus, when distally pointing to the far bowl on either side, the informant’s pointing finger was actually nearer to the proximal bowl. In order for a dog to perform accurately on these critical trials, it had to extrapolate an invisible vector from the angle of the informant’s arm towards the distal bowl. The results did not support an understanding of the referring function of

the pointing cue. When dogs chose the correct side of the informant, they tended to favor the more proximal of the two bowls (i.e., the one closer to the pointing gesture) regardless of which particular bowl was pointed at. Lakatos et al. (2012) also examined whether dogs directed by their owner's pointing cue to one of two informants simultaneously pointing and gazing at one of a pair of containers to their right and left would attend accurately to the cue of the indicated informant. Although dogs accurately chose the informant indicated by their owner, they did not accurately respond to the indicated informant's pointing cue. These findings suggest that dogs do not fully appreciate the declarative nature of pointing (i.e., pointing that directs attention to an entity from which information may be derived).

In a different study of a dog's understanding of the referring function of pointing, Tauzin et al. (2015) examined whether dogs process the identity of the object at the terminal destination of the pointing cue or only the location where they should respond to an object. Dogs were tested in an object-choice task in which two physically different plush toys were positioned left and right of an informant. On each trial, the informant pointed directly and momentarily while target gazing. Following this, the informant picked up both toys, turned 180°, and placed them back on the floor (i.e., opposite from their original locations). Each dog, after watching this procedure, was allowed to make a selection. Half the dogs experienced an ostensive condition in which prior to pointing, the informant called the dog's name and made eye contact, thus showing communicative intent. The other half experienced a non-ostensive condition to gain the dog's attention. Only dogs in the ostensive condition performed above chance. However, they chose whichever toy was at the indicated location more often than the particular toy originally indicated by the informant. These findings suggest that dogs understand the communicative intent of pointing but not that it refers to a particular object that may vary its location.

Finally, Miklosi and colleagues compared dogs and cats in their understanding of momentary direct pointing and dynamic direct pointing

using both proximal and distal pointing cues (summarized in Miklosi and Soproni 2006). Both dogs and cats responded above chance to each cue type, and for cats, but not dogs, performance was better with dynamic than momentary cues. There was no evidence of learning how to respond across trials in either animal.

### Goats, Horses, and Pigs

To examine whether other domesticated species beyond dogs could understand human-directed pointing cues, two early studies employed object-choice tasks with domesticated goats and horses. Summarized in Miklosi and Soproni (2006), McKinley and Sambrook (2000) tested the ability of four horses (*Equus caballus*) to follow human direct dynamic pointing. On each trial, an informant pointed distally to a target while moving her hand up and down. On half the trials, the informant stepped diagonally closer to the target and on the other half further from it. Although one horse performed above chance, this individual first ran his nose down the informant's arm before choosing the target suggesting that local and/or stimulus enhancement played a role in the horse's responses. In the second study, Kaminski et al. (2005) tested how domesticated goats (*Capra hircus*) responded to pointing cues in a two-alternative object-choice task. On each trial, an informant either repeatedly directly pointed at and touched the target while subject gazing or used dynamic distal direct pointing with gaze alternation. Of 23 goats tested, 13 (57%) and 5 (22%) responded above chance to the proximal and distal cues, respectively.

Later studies with horses and pigs appeared to confirm earlier observations that enhancement-type processes are influential in the successful responses of some domesticated species to an informant's pointing cues. Maros et al. (2008) tested 20 horses with various forms of pointing in a two-alternative object-choice task. Each was first tested with distal direct momentary pointing. None performed above chance. Next, the horses were tested on distal dynamic pointing, proximal momentary pointing, and proximal dynamic pointing with dynamic target gazing.

Between 2 and 6 performed above chance across conditions. However, on successful dynamic pointing trials, some of the horses tended to approach the informant's pointing hand before choosing the container on that side. Proops et al. (2010) tested how 28 horses responded to distal dynamic pointing as well as other cues in a two-alternative object-choice task. When responses were grouped together, the horses performed above chance in the pointing condition. However, again some horses that responded correctly to pointing cues first examined the informant's outstretched arm before choosing the correct target.

Recently, Nawroth et al. (2014) examined how 17 pigs (*Sus scrofa domestica*) responded to proximal dynamic pointing with dynamic gazing, proximal momentary pointing, distal dynamic pointing, and distal momentary pointing with the informant positioned between two containers in an object-choice task. Individually, 5 and 14 pigs, respectively performed above chance with proximal dynamic pointing and with proximal momentary pointing. None performed above chance in either of the distal pointing conditions. In a follow-up test, the informant changed locations to either behind the target where they remained without pointing or behind the nontarget where they pointed dynamically while gazing at the target. Nine pigs selected the target in the former condition but only one in the latter. Moreover, with both distal dynamic and proximal dynamic pointing, pigs often approached or touched the informant's pointing finger before choosing a container indicating that as with horses, enhancement-like processes likely influenced their responses.

## Undomesticated Animals

### Monkeys and Bats

Early studies of pointing comprehension in monkeys using object-choice tasks employed proximal direct dynamic pointing cues with results ranging from poor performance with cotton-top tamarins (*Saguinus oedipus*) to highly limited eventual success in rhesus monkeys, to either

eventual or immediate success with capuchin monkeys (*Cebus apella*) (summarized in Miklosi and Soproni 2006). Later studies using these same types of cues with capuchin monkeys (Essler et al. 2017) revealed generalization to novel informants within and across species. Studies with four species of bat (*Pteropus pumilus*, *Pteropus rodricensis*, *Pteropus conspicillatus*, and *Pteropus vampyrus*) were also limited to proximal dynamic pointing with subjects showing immediate success (Hall et al. 2011). Across these studies, findings of eventual success are subject to associative learning mechanisms, and those of immediate success to explanations of stimulus or local enhancement due to the very close proximity of the pointing cue and target.

### Apes

Perhaps not surprisingly, some of the earliest work investigating pointing in species other than humans focused on their closest relatives, apes. Although observational studies at that time suggested that apes in the wild do not readily point indicatively (Call and Tomasello 1994; cf. Halina et al. 2018 for recent positive examples), productive pointing to direct a human's attention to distal objects in conjunction with appropriate use of gazing was observed to emerge in captive enculturated apes with extensive human contact including exposure to pointing. For example, Call and Tomasello (1994) showed how two orangutans, Chantek who was highly enculturated, and Puti who had a more traditional captive upbringing, used pointing differently to direct a receiver. Both orangutans had previously been trained to point in limited contexts. In an initial test, they witnessed food being hidden in one of three containers that they pointed to when a receiver who had not witnessed the baiting entered the room. The receiver either retrieved the food directly if within reach, or, with a tool if out of reach. Next, they observed as both food and tool were hidden in different locations. This time when the receiver entered the room, only Chantek pointed immediately to a possible location of the hidden tool prior to pointing to the baited container and his performance improved over trials. Further tests revealed that both orangutans

pointed more often when the receiver was present than absent or away from the apparatus with their back turned. Chantek, but not Puti, pointed more often when the informant was facing forward with their eyes open than when they were closed. Later, during a test of pointing comprehension, an informant used distal momentary pointing accompanied by subject gazing to indicate which one of three containers had been baited, and then left the testing room. A receiver, ignorant to which container had been baited, entered the room and waited. Only Chantek pointed to the baited container above chance levels.

In another early study, Povinelli et al. (1997) tested seven chimpanzees on their understanding of direct static pointing. On each trial out of a subject's view, one of two boxes was baited and an informant adopted a static pointing position before the subject entered the room and responded. Each of the chimpanzees was first trained to respond to static proximal pointing (without gazing). The chimpanzees were next tested on static distal direct pointing either presented alone or with the informant target gazing or subject gazing. Combining the data from all pointing cue trial types, only one chimpanzee performed above chance. Next, Povinelli et al. (1997) tested the chimpanzees with variations of the pointing cue as well as variations of the informant's position while pointing. With the informant positioned between two containers, subjects could not understand elbow cross-body pointing whether it was accompanied by gazing or not. When the informant was positioned at the unbaited box, performance with elbow cross-body pointing accompanied by gazing was at chance and with elbow-cross-body pointing presented alone fell below chance (i.e., the subject chose the box closest to the pointing cue).

Four follow-up studies summarized by Miklosi and Soproni (2006) focused on ape comprehension of proximal and distal pointing cues with mixed results. Tomasello et al. (1997) found that none of six chimpanzees and only one of three orangutans (Chantek) responded accurately to proximal dynamic direct pointing to whichever of three containers was baited. In contrast, 17 of 24 thirty-month-old children performed

above chance. Using the same pointing cue accompanied by dynamic target gazing, Itakura and Tanaka (1998) showed above-chance performance for children ranging in age from 18 to 27 months, as well as for two chimpanzees and an orangutan. In the absence of gazing cues, Peignot and Anderson (1999) found that all four gorillas tested performed above chance responding to proximal dynamic pointing in a two-alternative object-choice task. Finally, Itakura et al. (1999) examined how four chimpanzees responded to distal dynamic direct pointing accompanied by gazing from either a human or a conspecific informant. No chimpanzee performed above chance with a conspecific informant, and only one was above chance with a human informant. However, this subject likely learned how to respond over the test.

In light of the generally poor performances by chimpanzees with pointing cues, Hare and Tomasello (2004) considered whether the cooperative nature of the traditional object-choice task was confusing to subjects, and whether having the informant act more competitively would yield better results. Using 12 chimpanzees, they compared performance in an object-choice task when an informant acted competitively versus cooperatively. During an introductory phase, chimpanzees attempted to find a baited container in the presence of an experimenter. For half the chimpanzees, the experimenter acted competitively (e.g., reacted negatively if the chimpanzee found the baited container) and for the other half acted cooperatively (e.g., praised the chimpanzee for finding the baited container). A test then ensued. Following a baiting procedure, the competitive informant reached his contralateral hand with fingers spread through a window towards the baited container while staring at it. In contrast, the cooperative informant reached through the window and pointed with gaze alternation at the baited container. Three of six chimpanzees exposed to the competitive informant were successful in finding the bait. None were who experienced the cooperative informant. Furthermore, chimpanzees that initially experienced success with a competitive informant were later successful with proximal pointing from a cooperative informant

with no evidence of associative learning across trials.

Using another strategy, Mulcahy and Call (2009) investigated how the position of the subject, the informant, and the containers might affect an ape's performance in an object-choice task with dynamic distal versus proximal pointing cues. Twelve chimpanzees, four bonobos, and three orangutans participated. The proximal pointing task was presented in the traditional manner used with apes in which a subject was positioned in close proximity to two containers on a single table when a pointing cue was delivered. In contrast, in the distal condition, the distance between the containers was more than four times that in the proximal condition, the informant was positioned between the containers instead of between and behind them, and the receiver was located farther from the informant as well as the containers. On each trial, the informant produced a dynamic long cross-body pointing cue accompanied by dynamic gazing. Performance accuracy collapsed over individuals and species was above chance in the distal condition but no different from chance in the proximal condition. Individually, eight chimpanzees, three bonobos, and one orangutan performed above chance with distal pointing while only one bonobo and three chimpanzees performed above chance with proximal pointing. Why under these conditions was there a marked improvement in ape' responses to an informant's distal pointing cue? Mulcahy and Call (2009) suggested several possibilities including that the position of the informant directly between the containers enhanced their contrast, that the substantial separation of the containers created an additional energetic cost of selecting the unbaited container that motivated the receiver to better focus its attention on the informant's gesture, and that the separation of containers also decoupled them from occurring in the same visual space as the informant's gesture and potentially competing with each other for the receiver's attention.

Using a similar strategy to Mulcahy and Call (2009) with further separation of the informant from the midline of the containers, Lyn (2010) showed that all six bonobos she tested responded

above chance to an informant's distal dynamic pointing cue accompanied by gaze alternation and performed better with distal than proximal pointing. In another study, Lyn et al. (2010) showed that immersing apes in a human-ape sociolinguistic environment significantly enhances their performance in responding to human pointing cues in object-choice tasks.

### Wolves

Studies of pointing comprehension in wolves (*Canis lupus*), the closest wild relative of dogs have been pursued largely to examine whether domestication of dogs lead to their ability to understand pointing cues. Hare et al. (2002) first compared how seven adult wolves and seven adult dogs responded to human dynamic proximal cross-body pointing cues in a two-alternative object-choice task in which pointing was accompanied either by gazing at the target or subject. Five and four dogs performed above chance respectively with each of these cues. No wolf performed above chance with either cue. Next, Miklosi et al. (2003) tested 4-month-old wolves that as puppies were individually raised by humans in homes and subsequently on a farm. Four wolves were tested with proximal and distal momentary direct pointing in an object-choice task. On initial trials, two wolves responded above chance to proximal pointing, but none to distal pointing, although one eventually learned how to perform with this cue. Follow-up tests in problem solving tasks revealed that dogs were much more inclined than wolves to gaze at a human when the task became insolvable. Finally, Viranyi et al. (2008) tested wolves and dogs with comparable human socialization, in the same object-choice tasks. In their initial experiment, three groups consisting of nine 4-month old wolves, eight hand-reared puppies, and nine pet dogs were compared. Each subject was tested with momentary direct distal pointing. The puppy and pet dog group each performed above chance and were not significantly different. In contrast, wolves, despite similar rearing histories and socialization as puppies, performed at chance both as a group and individually.

These studies appear to show uniformly that wolves do not readily understand pointing and perform poorly in object-choice tasks compared with their closest domestic relative, dogs, possibly because they are less prone than dogs to check on the focus of a human's attention. However, Udell et al. (2008) showed that this was not necessarily the case when the degree of human socialization for wolves was intensified (i.e., all wolves from 10 to 14 days old were hand-raised and had daily interactions with humans), the backgrounds of dogs were varied (pet dogs vs. shelter dogs), and the environmental conditions under which testing took place were modified (outdoors vs. indoors with cues from familiar vs. unfamiliar human informants). In their study, 8 wolves and 32 dogs (8 per condition) were tested with momentary direct distal pointing cues in an object-choice task under the following conditions: a familiar informant testing wolves and pet dogs outdoors; and an unfamiliar informant testing pet dogs outdoors, testing pet dogs indoors, and testing shelter dogs indoors. At the group level, only wolves tested outdoors and pet dogs tested indoors performed above chance. Although overall, both of these groups performed at similar levels, individually 75% of wolves performed above chance compared with only 37.5% of pet dogs. In the two conditions in which pet dogs at the group level did not perform above chance (i.e., those tested outdoors by either a familiar or unfamiliar informant), two dogs in each group (25%) performed above chance. Finally, individually, no shelter dog performed above chance. Thus, with intense socialization from an early age and under outdoor testing conditions, wolves not only can perform well with distal momentary pointing cues but outperform pet dogs tested under similar conditions, and do at least as well as pet dogs tested indoors.

### Elephants

Smet and Byrne (2014) reviewed studies of how two species of elephant responded to human-initiated pointing cues. Plotnik and colleagues (2013) tested seven Asian elephants (*Elephas maximus*) on their responses to momentary distal direct pointing in a two-alternative object-choice

task. Only one of the elephants performed above chance. In contrast, Smet and Byrne (2013) tested 11 African Elephants (*Loxodonta africana*) on their responses to dynamic distal direct pointing accompanied by gaze alternation and found that five elephants chose the indicated container above chance levels. Additional tests in which either the location of the informant or the pointing gesture itself was varied revealed that one or more elephants successfully responded to the following dynamic pointing cues: far direct pointing, long cross-body pointing, and forward cross-body pointing. However, all elephants were at chance when the informant produced an elbow cross-body pointing cue. In a follow-up study using a subset of these elephants, Smet and Byrne (2014) showed that at least some could follow momentary direct and cross-body pointing accompanied by gazing at the subject. There was no evidence that specific responses to pointing were learned across trials.

### Seals and Sea Lions

Miklosi and Soproni (2006) reviewed early work examining pointing comprehension in two species of pinniped. Shapiro et al. (2003) trained a gray seal (*Halichoerus grypus*) to respond to dynamic pointing made with an informant's right arm, and then showed that it could generalize to dynamic and momentary direct and cross-body pointing across different spatial configurations between the informant and distally placed land-based objects including with the informant positioned at the nontarget. Novel tests were also conducted with three distally placed objects in a pool, two positioned diagonally to the seal's left and right and the third placed out of view behind it. The seal responded accurately to an informant's points to the left and right objects but not to the object behind it. Shapiro and colleagues concluded that the seal likely did not understand the referential character of pointing but instead used signal generalization and experience from its initial operant training to respond to variations in pointing. In another study, Scheumann and Call (2004) tested how four fur seals (*Arctocephalus pusillus*) responded to different types of dynamic pointing using an informant's right arm in a two alternative

object-choice task. All seals performed above chance with direct pointing, cross-body pointing, and asymmetric pointing, regardless of whether target gazing accompanied or was absent from pointing cues. However, like several other species, performance was poor when the pointing cue was contained within the informant's body frame. An examination of performance across trials suggested that learning was not a factor in the seals' performances.

Recently, Malassis and Delfour (2015) showed in a two-alternative distal object-choice task that four sea lions (*Zalophus californianus*) with previous experience with human pointing responded at or near ceiling levels to direct momentary pointing with and without target gazing, and three of the four responded above chance to long cross-body pointing, elbow pointing, and foot pointing. A second experiment performed with the three more enculturated sea lions tested their understanding of the geometry of human pointing cues using a similar configuration of aligned near and far objects on each side of an informant, as was employed by Lakatos et al. (2012) with dogs. Each sea lion performed above chance with no overall significant difference in responses to the closer and farther targets and no learning effect across trials. In a final experiment, the informant was located at the apex of a triangle with each of two opaque barriers positioned along the legs. One object was placed directly in front of the informant while two others were each located behind the barriers and out of the sea lion's direct sight. On each trial, the informant used direct momentary pointing with target gazing to indicate an object. One sea lion responded accurately on initial trials to points directed at the visible and hidden objects.

### Parrots

Giret et al. (2009) examined how three African grey parrots (*Psittacus erithacus*) interpreted pointing in an object-choice task. Each parrot failed an initial test of distal momentary direct pointing accompanied by subject gazing and showed no evidence of learning how to perform accurately across trials. Subsequently, no parrot was successful with distal dynamic direct pointing

or proximal momentary direct pointing, but two responded above chance to proximal dynamic direct pointing accompanied by target gazing. Eventually, all parrots performed above chance with proximal dynamic pointing alone.

### Dolphins

Pack and Herman (2006) summarized studies of receptive and productive pointing competencies in bottlenose dolphins (*Tursiops truncatus*). Herman et al. (1993, 1999) tested how two enculturated bottlenose dolphins named Phoenix and Akeakamai responded to momentary pointing in several three-alternative object-choice tasks involving novel configurations of distally positioned objects. The dolphins had previously experienced pointing informally from trainers directing them to swim in a specific direction or to retrieve an object. In the earliest test, the objects were placed at the vertices of an equilateral triangle with the informant at the center on a surfboard facing the dolphin Phoenix. On each trial, the informant pointed directly at an object and then signed an action. Phoenix was highly accurate on initial trials in performing the indicated action to the indicated object. In later studies, Phoenix and Akeakamai were tested on their responses to momentary direct pointing with two novel configurations of three objects in which two were positioned diagonally left and right and the third was located behind the dolphin out of its immediate view (distances between the objects and the informant and dolphin were varied between the two configurations). Both dolphins performed above chance on first trials when the informant pointed to the left or right objects. Only Phoenix performed immediately above chance to points to the object behind her. Akeakamai was eventually successful after, for a brief period, the informant exaggerated his points by leaning slightly towards the central object. She also spontaneously understood long cross-body momentary points to the two side objects. In another study, Tschudin et al. (2001) showed that test naïve and relatively less enculturated dolphins spontaneously respond accurately to pointing cues within a two-alternative object choice task. Three of six public-show dolphins with no previous exposure

to human pointing as a signal responded nearly perfectly on tests of dynamic direct and cross-body distal pointing.

Substantial evidence that pointing directs a dolphin's attention and is understood as having a referring function was provided in tests of Akeakamai's immediate interpretation of imperative relational sentences within an artificial language system when one or two pointing cues were substituted for object signs. Within Akeakamai's language system, she understood the 3-item gestural sequence "Object 1"+"Object 2"+"Fetch," that instructed her to create a relationship by transporting the second named object to the first. For example, in response to the sequence Basket+Frisbee+Fetch, Akeakamai located the Frisbee from among numerous named objects in her habitat and transported it to the Basket. Given Akeakamai's high proficiency in carrying out these types of sentences, Herman et al. (1999) tested her responses when momentary direct pointing cues and/or a long cross-body pointing cues were substituted for one or both object gestures within relational sentences with three objects arranged distally to her right, left, and behind. Akeakamai was wholly correct on 28 of 36 novel relational sequences of this type.

Following this pioneering effort, Pack and Herman (2004, 2007) conducted a series of studies to further investigate the dolphin's flexibility in responding to pointing cues and its understanding of their referring function. Aside from showing that Phoenix, like Akeakamai spontaneously understood momentary cross-body pointing cues, Pack and Herman (2004) demonstrated that both dolphins spontaneously understood static direct and cross-body distal pointing within a two-alternative object-choice task. Both dolphins performed errorlessly or nearly so with each cue indicating that movement was not essential for understanding pointing.

In later work, Pack and Herman (2007) tested Akeakamai's ability to understand the geometry of direct momentary pointing using pairs of distal objects aligned on each side of an informant. On each trial, the informant pointed briefly at either the closer or farther object of a pair and then

signed an action to be performed to the indicated object. Akeakamai performed without error demonstrating that she could immediately decode the vertical geometry of pointing from the angle subtended between the informant's arm and his body.

Pack and Herman (2007) also tested Phoenix's ability to jointly attend to whichever of two distally placed objects was being pointed at by an informant and either perform a specified action directly to that object, or if the informant gave a "find-a-match" gesture, not respond directly to the indicated object, but instead determine its identity and find a match for it from among two alternatives at the opposite end of the pool. Momentary direct pointing and cross-body pointing cues were employed in both types of instructions. Phoenix's above-chance performance on initial trials showed that pointing directed her attention to the indicated object.

Bottlenose dolphins have also demonstrated spontaneous productive pointing to direct a human's attention. As reviewed in Pack and Herman (2006), Xitco and colleagues (2001) exposed two dolphins to human divers using an underwater visual/sonic keyboard to label different dolphin foods, toys, tools, and locations, as well as responding to labels by finding the corresponding item within the dolphin's habitat. Objects were regularly placed in transparent containers that the dolphins could see through but not open without either the direct assistance of a human or a tool. After 6 months of observing two divers modeling the use of the keyboard in communicative acts, each dolphin began to spontaneously point at containers using their rostrum and aligned body while alternating gaze between the container and a diver. In response to these cues, the diver opened the container and delivered its contents to the dolphin. Xitco et al. (2001) found that the dolphins were more prone to engage in monitoring a diver through gaze alternation when pointing to objects >2 m away, and when a diver was >2 m from the dolphin. In contrast, they tended to refrain from pointing when a diver was only 1–2 m from the dolphin and container and never pointed when a diver was absent. These findings suggested not only that the dolphins understood

that pointing would only be effective in the presence of a diver but also that a distant diver was more likely to require their attention to be drawn than one close by. In a second study, Xitco et al. (2004) investigated dolphin's pointing behavior as a function of a receiver's attentiveness. They positioned a dolphin on one side of a transparent divider where it viewed a diver on the opposite side bait one of two clear water-filled containers. The dolphin engaged in pointing and gaze alternation more often when the diver faced forward, than when he or she had their back to the apparatus, or swam away from it and hid. These studies suggest that dolphins can spontaneously use referential pointing.

## Discussion

### Who Gets the Point? Receptive Competencies

Based on differences in a receiver's responses to various manipulations in the object-choice task, some researchers have attempted to classify the understanding of pointing as either "low-level" or "high-level" (see Miklosi and Soproni 2006). Responses attributed to associative learning mechanisms and stimulus generalization were considered a "low level" of understanding, while a "high level" was reserved for responses that lent themselves to interpretations of pointing as a communicative tool indicating the informant's attention, terminal focus, and mental state. However, as noted by Miklosi and Soproni (2006), such extremes are likely not representative of the continuum of understanding of pointing, as a receiver might comprehend something of its communicative nature (i.e., an understanding beyond associative learning), but not that it represents the informant's mental state. Likewise, a receiver might understand that pointing is communicative but not fully appreciate its referring function.

As discussed earlier, a receiver's accurate initial responses to distal momentary direct and cross-body pointing presented in novel contexts without prior operant training of how to respond to pointing cues can provide evidence that the receiver understands pointing as a form of communication, and that its responses to pointing

are not the result of associative learning accompanied by generalization and/or some form of stimulus or local enhancement. Furthermore, if dynamic sustained distal pointing cues are employed, cross-body pointing as well as asymmetric pointing can help control for effects related to stimulus or local enhancement inasmuch as the pointing arm is closer to the nontarget than to the target. Evidence that the pointing cue is understood as having a referring function may be shown through accurate first trial performance in novel contexts to points towards objects out of immediate view, and to near and far objects in alignment on a side of the informant. The latter is especially helpful in demonstrating that the pointing cue is understood geometrically as the terminal destination of an informant's attention and not as a directive to move in a particular direction until encountering an object. Evidence that the receiver also attends to information available from an indicated object can strengthen arguments that pointing is understood referentially.

The studies reviewed here reveal animals whose responses to pointing place them along this range of understanding. The eventual rather than immediate success of several monkey species in responding to an informant's proximal pointing cues can be explained in terms of associative learning mechanisms. Because of the close proximity of an informant's pointing finger and the target in proximal pointing along with the absence of tests of distal pointing, the immediate successes with proximal pointing cues found in some studies with capuchin monkeys as well as in bats are confounded by the potential influence of stimulus or local enhancement.

Associative learning mechanisms accompanied by stimulus generalization were also implicated in a gray seal's success in responding to momentary distal pointing across variations in the cue and the informant's position, inasmuch as the seal first received formal operant training in how to respond to an informant's pointing cue and later failed to respond accurately in a novel context in which pointing was directed to an object out of its immediate view. Similarly, despite the success of several fur seals with dynamic pointing and asymmetric pointing, the

researchers remained uncertain whether their performance was due to generalization after earlier instrumental interactions with public show trainers, some form of social learning, or the product of a greater understanding of the pointing cue.

Associative learning and/or stimulus and local enhancement appear to be the most parsimonious explanation of the performance of parrots, horses, and pigs in object-choice tasks. Parrots failed tests with distal momentary pointing and distal dynamic pointing but were eventually successful with proximal pointing. With horses, the poor performance with distal momentary pointing and the behavior of many horses across three studies of first contacting the informant's outstretched arm in dynamic pointing before choosing a target on that side are consistent with an enhancement-like processes. Likewise, enhancement-like processes may also explain similar behavior in pigs.

The accurate initial responses of elephants, dogs, dolphins, and sea lions to an informant's distal momentary direct pointing cues, long cross-body pointing cues, and asymmetric pointing cues with the informant positioned at the nontarget, and data showing that these responses were not learned over the course of testing, suggest that these animals understand something about the communicative function of the pointing cue. Furthermore, additional studies with dogs, dolphins, and sea lions have helped clarify whether they understand the referential character of the pointing cue. With three objects arrayed to the sides and behind a subject, in which the horizontal angle of the informant's pointing cue indicated the object to be responded to, two dogs and a dolphin spontaneously understood such references. Additionally, a sea lion immediately understood points to objects behind opaque barriers. While dolphins and sea lions also understood the vertical geometry of the pointing cue, responding accurately to an informant pointing at either the nearer or farther of two aligned objects, dogs showed no such understanding, favoring the closer object, even when farther one was indicated. Thus, dogs appear more restricted than dolphins or sea lions in their understanding of the referring function of pointing. This

apparent difference seems consistent with the findings of Pack and Herman (2007) that a dolphin derived identity information from the object its attention was directed towards by a pointing cue, either finding a match for this object or responding to it directly depending upon the instruction following the cue (i.e., an understanding of declarative pointing) (reviewed in Pack and Herman 2006), compared to dogs who, when the indicated object in a two-alternative object-choice task switched locations with the nonindicated object, tended to focus attention on the original indicated location rather than on the original indicated object (i.e., failing to focus on the identity of the object being pointed at) (Tauzin et al. 2015).

Regarding ape' understanding of pointing, as described above, early studies seemed to indicate that with some exceptions, chimpanzees, orangutans, and gorillas performed poorly in object-choice tasks unless the tip of the informant's pointing finger was positioned proximally to the baited container and, for chimpanzees, if an informant acted competitively instead of cooperatively. However, in many of these studies, subjects were located proximally to the alternative containers when the informant pointed. In contrast, in object-choice tasks with species such as dogs, elephants, sea lions, and dolphins, subjects were positioned distally to the alternatives when receiving the informant's cue. In light of this, more recent studies by Mulcahy and Call (2009) and Lyn (2010) located subjects and informants distally from alternative objects. In this configuration, bonobos, chimpanzees and orangutans responded successfully to an informant's distal dynamic pointing accompanied by gazing cues. Lyn et al. (2010) also showed that enculturation within a human-ape communicative context can play an important role promoting success in object-choice tasks. It remains to be seen when both of these factors are taken into account whether apes will demonstrate an understanding of the referring function of pointing through accurate responses on initial trials with momentary distal direct and cross-body pointing, distal pointing in novel contexts to objects out of view, and pointing towards a distal object when another distractor object lays along the same path.

### Productive Pointing

Tomasello (1995) noted that for pointing to be considered referential, it should be closely coordinated with the receiver's attention, which can often be inferred from the receiver's face or body orientation (e.g., informant facing the target with eyes open). As noted earlier, other than a few recent observations of pointing by chimpanzees in the wild (Halina et al. 2018), there is currently little evidence that animals in the wild use this cue to direct the attention of others. Nonetheless, in some cases, pointing behaviors have either been explicitly taught to animals, or have spontaneously emerged in enculturated animals during social activities with humans (e.g., Meunier et al. 2013; also see reviews by Call and Tomasello 1994; Pack and Herman 2006). In both cases, a central issue is determining what the animals understand about the pointing cues they employ. That is, does a subject that points appreciate the attention-directing function of that gesture, or is pointing employed solely as performative to produce a particular outcome. To make this distinction, researchers have examined whether animals point in triadic transactions to distal objects, whether pointing is employed flexibly to indicate objects other than food, and whether pointing is coordinated with the receiver's presence and attention. With regard to the latter, a strong indicator of the intentionality of pointing in human infants, and in nonhumans, is when this cue is accompanied by gaze alternation between the target and the intended receiver. Meunier et al. (2013) listed this as well as the use of other attention-getting behaviors such as vocalizations to supplement pointing cues, and the persistence of an informant in pointing when initial attempts fail in defining a child's ability to intentionally attract and direct a receiver's attention through pointing.

As shown above, studies with enculturated apes and bottlenose dolphins have revealed the spontaneous emergence of pointing behaviors that are contingent on the receiver's presence and attentiveness (Call and Tomasello 1994; Pack and Herman (2006), which reviewed these studies, with Xitco et al. 2001, 2004). As with intentional pointing in human infants, pointing

in these animals was often accompanied by gaze alternation between the indicated object and the receiver. For dolphins, gaze alternation occurred most often when the receiver was located distally to the target being indicated, providing additional evidence of its understanding of the contingencies under which pointing as a referential signal is effective. In chimpanzees, evidence suggests that they point intentionally to indicate particular objects. For example, if they point at a specific food item and receive an alternative food, their pointing at the original item persists (Halina et al. 2018). Pointing-like behaviors in dogs, on the other hand, have revealed a sensitivity to the presence of a human receiver, but not necessarily to the receiver having to be face forward during pointing events, although this understanding seems to occur sometimes in nonpointing activities (Hare et al. 1998).

That enculturation is not a requisite for displaying communicative intentionality and referential understanding in pointing was recently shown by Meunier et al. (2013). After nine non-enculturated olive baboons (*Papio anubis*) were trained to display an outstretched arm and whole-hand pointing gesture to obtain a raisin that was distally positioned and out of reach, they each observed as an experimenter baited one of five distally positioned containers. Then, a receiver whose back was turned during the baiting event approached the containers, examined the contents of whichever container a baboon subject pointed to, and if the indication was to the baited container, delivered the bait to the baboon. Meunier et al. found that baboons pointed more often and gazed longer at the receiver and the baited container when the receiver faced them and was within reach of the baited container than either when the receiver was face forward but not yet within reach of the baited container or had their back turned to the containers. Baboons also engaged in more gaze alternation when the informant was face forward and either within or just out of reach of the baited container than when their back was turned.

Regarding the criterion of intentionality in productive pointing that an informant should persist in pointing cues when initial attempts fail,

Halina et al. (2018) examined this using a gestural-persistence paradigm in which the pointing cues of three bonobos and nine chimpanzees towards hidden food in the presence of a human receiver were either successful (the human receiver looked at the object being indicated), or unsuccessful (the human receiver looked at something different than what was being indicated). Halina et al. (2018) predicted that when pointing was initially unsuccessful, subjects would persist in pointing more than if pointing was initially successful. The results indicated that although the apes gestured in a communicative manner (i.e., more time was spent employing points with eye contact than without eye contact), they spent more time pointing at food when they successfully directed the receiver's looking behavior than when they failed. To explain these findings, Halina et al. (2018) proposed that within the context of a task in which subjects point towards food that a receiver cannot see, the pointing of an ape has two goals, first to direct the receiver's attention, and if this is successful to request the indicated food.

### **The Issue of Domestication and Other Biological Foundations for Understanding Pointing**

Based on studies showing relatively superior performance by domesticated dogs in attending to an informant's pointing cue in an object-choice task, compared to apes, our closest relative, or wolves, the closest wild relative of dogs, several researchers have proposed that the ability of dogs to "read" human pointing cues evolved during the process of domestication, either because it had been directly selected for, or as a by-product of selection against aggression and fear toward humans (Hare et al. 2005), or simply as a product of domestication in general (Kaminski et al. 2005). Consistent with the latter view, like dogs, domesticated cats have been shown to be proficient in responding to human momentary distal pointing (Miklosi and Soproni 2006). Also, Kaminski et al. (2005) demonstrated that domesticated goats were capable of accurately following dynamic distal direct pointing cues. However, because no tests of either dynamic distal cross-

body pointing cues or momentary distal pointing cues were conducted, it is difficult to eliminate the possibility that enhancement-like processes may have influenced the goats' performances. As noted earlier, the behavior of both domesticated horses and pigs in first contacting the informant's outstretched arm during dynamic pointing indicated a likely role of stimulus and/or local enhancement in their success. Additionally, horses showed no proficiency with momentary pointing cues, while pigs were only successful at momentary cues accompanied by target gazing. Although no such informant touching was reported for goats, as pointed out by Herman et al. (1999), a sustained pointing cue potentially provides a fixed "trail" that the receiver can follow and continually refer to as it approaches the target (Pack and Herman 2006). Thus, a general effect of domestication on the ability of an animal to follow human pointing cues seems insufficient to capture apparent differences in the proficiency of various domesticated animals in responding to pointing.

Hare and colleagues (2002) concluded that their findings of significant differences in how domesticated dogs and wolves responded to pointing strongly supported the hypothesis that the social-communicative skills between dogs and humans evolved during the process of domestication and represented a case of evolutionary convergence of particular sociocognitive abilities of dogs with those of humans through a phylogenetic process of enculturation. To test whether the receptive pointing competency in domesticated animals like dogs is a result of direct selection for this ability or a by-product of selection against fear and aggression toward humans, Hare et al. (2005) compared pointing comprehension in experimentally domesticated fox kits who had been selectively bred over 45 years to approach humans fearlessly and nonaggressively versus a control group without this deliberate selective breeding background, as well as in dog puppies. Neither fox group were bred for or tested on their ability to use human gestural cues. Among various tests conducted, Hare et al. (2005) compared the responses of 11 experimental foxes and 11 dog puppies to an informant's pointing cue. The informant lay on the floor between two containers and

pointed directly and dynamically at the baited container while gazing at it. There was no significant difference in the choice accuracy of experimental foxes and puppies, both groups performing above chance. Above-chance performance in a subsequent test of dynamic direct pointing accompanied by dynamic gazing was also shown in experimental and control foxes. However, in this case, the experimental foxes used the cue more often than the control foxes. Based on these results and other comparisons of measures of social interaction with humans and objects, Hare et al. (2005) suggested that socio-cognitive evolution allowing for proficiency in understanding pointing cues had occurred in experimental foxes, and possibly domestic dogs, as a correlated by-product of selection on systems mediating fear and aggression.

In addition, more recent studies with wolves showing that when they are reared with substantial human socialization and tested at following momentary distal pointing cues outdoors, they perform better than pet dogs tested under similar conditions and at least as well as pet dogs tested indoors (Udell et al. 2008), and also studies showing that kennel dogs with limited human interaction perform poorly in response to dynamic distal pointing cues compared with pet dogs of similar breed, sex, and age (D’Aniello et al. 2017), indicate that ontogenetic factors and environmental factors also play an important role in the responses of wolves and dogs to human pointing gestures.

The findings of Udell et al. (2008) as well as those with undomesticated species such as elephants, dolphins, and sea lions indicate that domestication itself is not a requisite for understanding an informant’s pointing cue. Kaminski et al. (2005) suggested that considerable interactions with humans promote the ability of undomesticated species to use human-initiated communicative cues such as pointing. However, it may also be that certain natural behaviors within a species’ repertoire provide a cognitive foundation that an animal can build upon to make meaningful responses to an informant’s pointing cue. For example, Herman et al. (1999) suggested that the proficiency with which bottlenose dolphins comprehend and produce

distal pointing cues derive or generalize from their use of echolocation to inspect distal objects including those hidden from view (Pack and Herman 2006). Dolphin echolocation is projected in a narrow directional beam that is often in line with the longitudinal axis of the dolphin’s rostrum and body. Thus, when a dolphin echolocates on an object, its aligned rostrum and body are essentially pointing to that object, although not necessarily with the intent of drawing another’s attention to the object of interest. Nonetheless, because dolphins can eavesdrop on each other’s echolocation signals, an observing dolphin can potentially understand the terminal focus of an echolocating dolphin’s attention.

## Conclusion

From its infancy in the early 1990s to the present time, the study of pointing in nonhumans has become a rich and robust enterprise. Evidence indicates that while some species appear to rely on associative learning, and/or stimulus or local enhancement to respond accurately to pointing, others derive a deeper understanding of that cue’s communicative value including its referring function. Broad-based approaches employing different forms of momentary distal pointing in object-choice tasks, as well as in novel contexts and using different types of tasks have been helpful in distinguishing between these interpretations of an animal’s understanding of pointing. Several species have also been shown capable of producing points to specific objects in accordance with a receiver’s attention state. Although domestication may have influenced pointing comprehension in some species, it is not a requisite inasmuch as there are marked differences in how different domesticated species react to and interpret pointing to distal objects, as well as the fact that several undomesticated species can understand these same cues. Pointing as a unique form of nonlinguistic communication involving joint attention that spatially directs attention in a manner that can benefit both the informant and the receiver remains of broad comparative interest. Future efforts to study pointing in animals should

continue to expand those species under investigation, and employ diverse approaches to examine the degree to which an informant's pointing cue directs a receiver's attention and is understood referentially, the types of information an individual glean from the subject its attention is being directed towards, the biological processes, cognitive mechanisms and social experiences that foster an understanding of pointing, and what a receiver and an informant understand about each other's mental experience during pointing events. Finally, the studies reviewed above varied widely in sample size. Clearly, in those studies highly limited in subjects, if even one demonstrates immediate understanding of momentary pointing to distal objects under novel conditions that suggest referential comprehension, that capability is within the cognitive potential of the species. However, if none demonstrate this ability, it is difficult to arrive at any firm conclusions regarding pointing comprehension at the species level. On the other hand, with larger sample sizes and greater power, the finding that only one or a few subjects out of many tested comprehend the pointing gesture or alternatively that the majority comprehend this cue allows for inferences about the different predispositions of the species. Given this, it would be beneficial for future studies to augment the number of subjects examined for their understanding of pointing. However, in those instances in which generating a large sample size is impractical, in the least studies should diversify the ways in which pointing is examined within individual subjects to allow for converging evidence of their cognitive understanding of this cue.

## Definition

Pollution is the introduction of the pollutant or the waste material that deteriorates the quality of environment. It is caused by the pollutants that include chlorofluorocarbons, carbon monoxide, chemical fertilizers, particulate matter,

microplastics, pesticides, herbicides, heavy metals, municipal solid waste, etc.

## Forms of Pollution

There are majorly ten different types of pollution present in an environment along with their pollutants, and those include:

- (a) **Air Pollution** – It is being defined as the presence of particulates and gaseous pollutants in the environment which contaminate the air and deteriorate the air quality. The pollutants include carbon monoxide, sulfur dioxide, chlorofluorocarbons, nitrogen oxide, and particulate matter (PM) that are all produced by motor vehicles and industry. Significant studies are there to support the relationship between the particulate matter and neurodegenerative disorders (Fu et al. 2019). In addition to this, cement plant contributes for approximately 5% of carbon dioxide emission (Hendriks et al. 2004) which results in respiratory disorders and reduction in lung function (Fell and Nordby 2017) if the dust total levels exceed  $4.5 \text{ mg m}^{-3}$ . These pollutants are also associated with high resting blood pressure (Bacardit et al. 2018), chronic obstructive pulmonary disease (Trnjar et al. 2017), and premature deaths (Samorodskaja et al. 2017). Biomass fuels such as animal dungs, coal, charcoal, wood, etc. produce mix of pollutants having more than hundred times particulate matter than outdoor air pollution. This contributes to almost 2.9 million deaths worldwide and also causes tuberculosis among children (Sumpter and Liu 2013). Particulate matter is also being associated with cardiovascular disease including the events like myocardial infarctions (Brook et al. 2010).
- (b) **Light Pollution** – It includes the processes such as over illumination and astronomical interference. Photocatalytic reduction of carbon dioxide to carbon monoxide and organic compounds causes light pollution. The artificial light at night (ALAN) disrupts the

biological clock and suppresses the nocturnal production of melatonin (Reiter et al. 2007). This also results in increased cancer risk (Blask 2009; Davis and Mirick 2006; Kantermann and Roenneberg 2009; Stevens et al. 2007, 2014). Sleep disturbances have also been found due to artificial light and have an impact on aging and metabolic process. Artificial light is also associated with the problems like heart diseases, mood swings, and obesity (Gangwisch 2014; Stevens 2009).

- (c) **Noise Pollution** – This includes the pollution caused by roadway noise, aircraft noise, industrial noise, as well as the sound of SONAR. It is referred to as a kind of unwanted sound. It is a form of pollution that causes threat to health. Highway, rail, and air traffic are major sources of environmental noise pollution. Noise pollution can be natural, or it can be man-made. As population is growing day by day, noise is becoming more numerous and causes more annoyance. Noise is not only harmful but also has adverse health effects. Our body responds or fights with noise resulting in various kinds of changes like hormonal, vascular, etc. The noise of engines, jet engines, radio, television, toys, train horns at crossing are of great concern. The noise of machines and other man-made activities can be tolerated because they serve an important purpose to the society and welfare to mankind. General exposure of sound to levels less than 70 decibels does not cause any impairment. Major effects of noise pollution are hearing impairment, interference with spoken language, sleep disturbances, cardiovascular disturbances, mental health disturbance, annoyance reaction, etc.
- (d) **Plastic Pollution** – It is referred to as the accumulation of plastic bodies over the land and water surface. It is ubiquitous all around the environment. It affects wildlife, nature, and human habitat. Plastic has the property of buoyancy and durability due to which it accumulates in environment and persists endlessly. Plastic degrades as hazardous waste (Rochman et al. 2013) in the environment. Globally it is analyzed that in North Pacific, approximately 21,290 metric tons of floating microplastic was found. Threat of plastic pollution has been ignored for a long time. Small plastic pellet and granules are also equally disastrous. Some plastic particles are found in the stomach of seabirds which have also increased during past 10–15 years. Over past 20 years, polychlorinated biphenyls have polluted marine food webs which result in reproductive disorders, disturbances in hormonal levels, and increased risk of disease. Polythene bags are being used for a long time and are being accumulated in terrestrial as well as marine environment.
- (e) **Soil Pollution** – The presence of pollutants in soil results in contamination of soil. Pollutants like nitrates, phosphate, and other trace elements deteriorate the quality of soil. Nitrogen forms include nitrates, nitrites, and ammonia. Many phosphorous compounds are also present in soil as contaminants. Presence of heavy metals also enhances the soil pollution which results in lowering of the overall density of earthworm and other microfauna. Cadmium compounds are used in rechargeable nickel – cadmium batteries. Cigarette smoking is also one of the major sources of cadmium exposure. Lead contamination is also widespread these days. Various statistical results show that lead content in dust and soil derives from anthropogenic resources. Lead in soil is also being associated with the local traffic. Elevated levels of copper are also being found in some areas.
- (f) **Radioactive Pollution** – It results from the activities such as nuclear power generation and nuclear weapon manufacturing and deployment. It is hazardous because it releases radioactive substances and ionizing radiations like alpha, beta, and gamma rays. Degree of their effectiveness varies with the type of radiation and its concentration. The nuclear reactor and nuclear weapon contaminate air, soil, people, plants, etc. Many radioactive activities are naturally occurring such as elements like uranium and thorium, and their

decay products are present in soil and rock. Naturally detected radon gas is being equally responsible for radioactive pollution. Carbon-14 is continuously created by cosmic rays in humans. Radioactive contamination can affect the body through the processes like ingestion, inhalation, absorption, or injection with a fixed dose of radiation. Radioactive contamination can also occur in our body as the result of eating contaminated plants and animals or drinking contaminated water or milk from animals that are exposed to these kind of radiations.

- (g) **Thermal Pollution** – This pollution occurs as a result of change in temperature of water which is caused by human activities such as use of water as a coolant in power plants by industrial manufacturers. The sudden change in temperature of water affects the oxygen content which directly or indirectly affects the composition of ecosystem. Increase in temperature decreases the level of dissolved oxygen of water. This affects the aquatic animals such as fish, amphibians, and other aquatic organisms. Thermal pollution also increases the metabolic rate of aquatic animals, such as enzyme activity, due to which these organisms consume more food in a shorter time than if their environment were not changed (Goel 2006). A large increase in temperature leads to denaturation of enzymes by breakage of hydrogen and disulfide bonds which decrease the enzyme activity in aquatic organisms and may cause the problems such as the inability to break down lipids, which will lead to the condition of malnutrition. Abrupt change in water temperature will lead to the death of aquatic organisms especially fish (Laws 2000; Chiras 2012).

- (h) **Visual Pollution** – It refers to the presence of municipal debris, motorway billboards, overhead power lines, strip mining, open storage of trash, etc. It is basically the impact of pollution which impairs the visibility to view the things by disturbing the environment. Basically overcrowding of an area causes visual pollution. It can also be defined as the whole of irregular formations, which are

frequently found in nature (Yilmaz 2011; Nagle 2009). Exposure to visual pollution results in distraction, eye fatigue, decreases in diversity, and loss of identity (Yilmaz 2011). High-rise buildings, if made, are not planned properly than it can bring adverse change to the visual and physical characteristics of a city, which may reduce said city's readability (Yilmaz 2011).

- (i) **Water Pollution** – It is the discharge of wastewater from either commercial activity or from industries. It also includes discharge of untreated domestic waste and contaminants like chlorine that releases waste and urban runoff water that contains chemical fertilizers and pesticides including human feces. The prolonged unchecked industrialization and urbanization has polluted the water bodies. Synthetic chemicals disperse into lakes and streams from atmospheric fallout, for example, natural seepage problems of oil and polycyclic aromatic hydrocarbons (PAH) into the continental shelf and beaches pose a health problem. High values of heavy metals are frequently documented in the peri-urban (Singh et al. 2010) and can be extremely toxic to aquatic organisms as well as to humans, where long-term ingestion of water polluted with heavy metals can be devastating, leading to the development of a number of cancers, neurological disorders, and even death.

## Cost of Pollution

Pollution has its own cost (Harvey 2016). Many manufacturing activities cause air pollution that imposes health and cleanup costs on whole of society. A manufacturing activity that causes air pollution is an example because a firm's production reduces the well-being of others which is not compensated by the firm (Gruber 2013). If we take an example of a laundry firm that exists near a polluting steel manufacturing firm, then definitely there will be increased costs for the laundry firm because of the dirt and smoke that are produced by the steel manufacturing firm

(Kolstad 2011). Due to this external costs created by pollution, the manufacturer will produce more and more of the product than would be produced if the manufacturer were required to pay all associated environmental costs. If some external benefits are there such as in public safety, less of the good may be produced and the producer was to receive payment for the external benefits to others. But it was found that goods and services are continuous in production; therefore the products that produce pollution tend to be overproduced and underpriced because the externality is not being priced into the market (Gruber 2013).

Pollution also creates the cost for the firms that produce the pollution. Sometimes these firms are forced by regulation, to decrease the amount of pollution that they are producing. The cost associated with that is called abatement costs or marginal abatement costs if measured by each additional unit (2018). In 2005 it was estimated that pollution abatement capital expenditures and operating costs in the USA amounted to nearly \$27 billion (2018).

## Sources and Causes of Pollution

Pollution has two types of sources, viz., point sources and nonpoint sources. **Point** sources are basically localized and confined identifiable sources of contaminants, for example, power plants, refineries, mining factories, wastewater treatment plants, etc. On the other end, **nonpoint** sources are those which are distributed widely over a geographic area, such as a watershed. Nonpoint sources also cover a wide range of moving sources such as cars, buses, and trains. Though each of these is a point source, they are mobile and thus spread their summative impact over a wide geographic area. Urban runoff can be considered as a typical nonpoint source of pollution, where the contaminant load is considered to be the sum of thousands of small point sources within the watershed.

Types of contaminants are basically classified as follows.

## Anthropogenic Sources

These sources can be broadly divided into two classes: hydrophobic compounds and hydrophilic compounds. As the name suggests, hydrophobic compounds are those that are not at all soluble or very less soluble in water, whereas hydrophilic compounds are largely soluble in water. Hydrophobic organic contaminants (HOCs) are considered to have been class of compounds which are most problematic and the most studied. The hydrophobic contaminants are of great concern because of two reasons. Firstly, due to their hydrophobicity, they have a tendency to accumulate in biota, including humans, and their elevated concentrations show adverse effects (Mackay and Fraser 2000). Secondly, the hydrophobic compounds can be easily extracted and concentrated from environmental media and thus more easily detected, quantified, and studied by various instrumental and analytical methods. In environment these hydrophobic organic contaminants are often stored in sediments. Their storage is present mainly due to hydrophobic interactions of these organic contaminants with humic substances associated with sediment particles (Karickhoff et al. 1979). HOCs adsorb to humic substances due to the presence of natural organic matter in the water column increase HOC solubility (Chiou et al. 1986). Humic substances play a role in mobilizing HOCs from sediment to water column. Thus, it can be explained why the concentration of HOCs is higher in sediments than in the water column (Caron et al. 1985; Suffet et al. 1984).

## Plastic and Marine Debris

The growing amount of plastic in environment and other trash material in the world's oceans and lakes is of immediate concern. Accidentally most of the times, trash is dumped directly into the ocean, mostly from ships and offshore platforms, but more frequently it is carried by rivers and streams or blown in by wind. Safe land filling and trash pickup are important so that they cannot resort to open dumping. Globally we find improper handling of waste in all countries. Circular patterns created by winds and the Coriolis effect from the rotation of the earth rotate millions of tons of plastics, and other marine

debris in the ocean get concentrated in giant gyres. Example of one such giant vortex that accumulates trash is called the Great Pacific garbage patch. It lies in the North Pacific Subtropical Convergence Zone and stretches from California to Japan. At present there are five major garbage patches that are located in different regions including North and South Pacific, North and South Atlantic, and most probably Indian Oceans. More garbage is accumulated below the middle of these gyres rather than elsewhere, but some amount of garbage move in and out, while the rest concentrate at the middle. Plastics can take possibly hundreds of years to break down completely in comparison to natural materials such as cotton that can biodegrade very rapidly. Sunlight and physical stressors can break down plastic trash such as water bottles to the extent that they can be converted into smaller and smaller bits, which form the soup of marine debris that consists of tiny pieces of plastic. Birds and fish sometimes ingest the plastic as food by mistake. One can find more plastic concentrated in certain parts of these gyres than biomass. PCBs and other pollutants are also adsorbed by these gyres. Thus when an organism ingests plastic, it also ingests the contaminants which are present on the plastic. Plastics contain toxins such as bisphenol A which is categorized as endocrine-disrupting chemical, or it may contain phthalates, or vinyl chloride, depending on the type of plastic. These chemicals are persistent in nature, and bioaccumulates will be transferred throughout the food chain. One should be very concerned because it is probable that these chemicals are likely to be found in fish. When these plastic pieces break down into particles of less than 1 mm in diameter, they are called microplastics. Most microplastic is being created from the decomposition of trash and also enters the environment from sewage discharges carrying personal care products. These microplastic beads are being used to make good facial scrubs and in various cosmetics and toothpastes. But zooplanktons ingest microplastics (Cole et al. 2013) which is one of the growing concerns in marine biota, and this all has led to a federal ban of

microplastics. After seeing more trash than fish on a vacation dive the Ocean Cleanup is basically a nonprofit organization out of the Netherlands founded by Boyan Slat, given the design a solution to the problem. After a TED talk and crowd funding campaign, his organization started studying the marine debris problem and is designing technology that will aid in ocean cleanup. This organization believes to have removed half of the plastic in the Great Pacific garbage patch in approximately 10 years. Many other organizations contribute to beach cleanup activities that collect marine debris.

### **Metals and Metalloids**

Most of the water contamination is triggered by anthropogenic factors like industrial effluents leaching into the ground. Groundwater pollution is tough, but once polluted it can be extremely difficult to get rid of. The prolonged unchecked industrialization and urbanization has polluted the two major water bodies. Overexploitation of groundwater resources due to population explosion is also making the problem more tedious in many regions of India as well as in other countries. Heavy metals are likely to rush in from industrial waste dumped untreated into water systems, while nitrates may be distributed on to the surface due to excessive and prolonged use of fertilizers. Arsenic and fluoride are commonly found in groundwater where chemicals have leached from the bedrock due to overexploitation of the source. Fluoride, arsenic, and iron are known to have caused encephalitis, jaundice, and typhoid, mostly among the poor who live in dismal sanitation conditions. High content of heavy metals in water and sediments in river Ganges downstream have been reported (Singh et al. 2005). Arsenic distribution is also affected by anthropogenic activities, such as mining and smelting operations, coal-fired combustion, and use of agricultural herbicides, pesticides, and medicinal and cosmetic products (Orloff et al. 2009), but the major source of As, in general, is chemical weathering of rocks (Bhattacharya et al. 2007). Lead is a contaminant in food and water. The unregulated discharge of

industrial wastes is also seen to pose significant risks to the food system (Marshall et al. 2017). The main contaminants identified within the effluents of these industries include high levels of organic pollutants as well as high concentrations of heavy metals. Human risk was assessed in people exposed to trace metals using exposure risk assessment model indicated. Arsenic was the most important pollutant causing non-carcinogenic and carcinogenic concerns, particularly for sensitive children. As, Sb, and Se were the largest contributors to chronic risks, while Ni, Al, Fe, and Ba were the least contributors in both the dry and rainy seasons (Zhang and Li 2010). The levels of these contaminants in the river and groundwater are consistently above permissible limits, and as a result, the water is considered unfit for recreational activity and the sustenance of aquatic organisms (Rizvi et al. 2015).

### Nutrients

It is basically a form of water pollution that contains contamination by increased input of nutrients. This is being primarily the cause of eutrophication of surface waters, in which overuse of the nutrients like nitrogen and phosphorus stimulates algal growth. There can be various sources of nutrient pollution that include the following:

- (a) Runoff water from farm fields and pastures.
- (b) Various kinds of discharges from septic tanks.
- (c) Emissions caused from combustion.
- (d) Excess nutrients can potentially lead to excess growth of algae known as algal blooms.

Species composition shifts, feed web changes, light limitation, excess organic carbon dissolved oxygen deficits (environmental Hypoxia), toxin production, excess nitrate in drinking water and disinfection by product are the common cause of Nutrient Pollution.

Nitrates and nitrites are naturally occurring, but their increased levels are because of the use of excessive fertilizer that goes into surface and groundwater. Other sources include animal manure or other chemical and factory discharges.

### Radionuclides

They are basically inorganic contaminants which are unstable isotopes that lead to radioactive disintegration to become more stabilized. An isotope of an element has a specific number of nucleons (protons and neutrons). Almost all elements have radionuclide; many of them are naturally occurring, but due to human activity, they become enriched in environment such as elements released from nuclear power plants, mining activity, various medical wastes, or from atmospheric deposition that came from nuclear bomb testing. For example, hydrogen exists in three isotopic forms, viz., hydrogen-1 and hydrogen-2 that contain one and two protons, respectively, and hydrogen-3 also known as tritium which rarely exists and is the result of nuclear power activity. Uranium also exists as a natural radioactive isotope in two forms, that is, uranium-236 and uranium-239. Radium and thorium are also naturally occurring radioisotopes. Groundwater near nuclear power plants have increased levels of several radionuclides, including tritium, radium-228/226, and strontium-90. Some organisms have adapted the ability to repair tissue damage upon exposure to low levels of ionizing radiation due to ubiquity of radionuclides. But when they are enriched in water, they are expected to pose a threat to life.

### Effects of Pollutants on Human Health

Till now in this entry, many pollutants have been described; each of these pollutants has adverse effects on human health. Some effects due to different kinds of pollutants are listed below.

#### Air Pollutants

- Breathing polluted air causes higher risk for asthma and other respiratory diseases.
- Decreased lung function of healthy individual and respiratory inflammation.
- People are at higher risk of cancer as most air pollutants are categorized as carcinogens that include various kinds of gases like CFCs, methane, etc.

- In city crowd coughing and wheezing are most commonly observed.
- Endocrine, reproductive, and immune system are at a great risk.
- Higher incidents of heart problems are being associated with particulate matter.
- Global warming is occurring due to increased level of carbon dioxide in atmosphere which is a result of increased man-made activities.
- Biomagnifications are occurring in food chains due to the accumulation of these toxic elements into plants and water resources because animals eat these contaminated plants that travel up to their body organs.

### **Water Pollutants**

- Many diseases such as amoebiasis, typhoid, and hookworm are associated with polluted drinking water.
- Water is exposed to heavy metals such as lead, arsenic, nickel, and chromium and pesticides (DDT, BHC, etc.), and hydrocarbon causes various hormonal and reproductive problems, leading to the damage of the nervous system, liver, and kidney. Moreover it leads to different types of cancer like bladder cancer, liver cancer, etc. Exposure to mercury may cause Parkinson's disease, Alzheimer's, and heart disease and eventually leads to death.
- If a beach is being polluted, then it may result in diseases like hepatitis, diarrhea, encephalitis, gastroenteritis, stomach aches, and vomiting.
- Pollutants in water affect marine life which can be one of our food sources.

### **Nutrient as Pollutants**

- Infants drinking excess of nutrient-contaminated water may become seriously ill and may go into a coma and can possibly die.
- It can result in complications like shortness of breath and blue baby syndrome, also known as methemoglobinemia, wherein a less percentage of the hemoglobin in the blood is oxidized and unable to carry oxygen.
- The mechanism is not completely clear, but it involves a role of methemoglobin (MetHb) in reducing the binding of nitric oxide

(NO) which allows nitric oxide to readily diffuse to neighboring cells; those results in activation of signaling pathways of vasodilation that leads to hypoxia.

### **Soil Pollutants**

- The presence of pollutants, contaminants, and toxic chemicals in the soil in higher concentration than normal has negative effect on wildlife, plants, humans, and ground water.
- Waste disposal, agricultural activities, acid rain, and accidental oil spill in soil influence health of humans, result in decreased growth of plants, decrease soil fertility, and change the soil structure.
- Soil pollutants mainly lead to the death of plants and complete reduction of the agricultural viability of soil.
- Soil pollutants are equally dangerous to animals because animals ingest plants that are exposed to soil pollution and they may die.
- Human consumption of such plants may lead to heart, kidney, and liver failures as well as cancer.

### **Conclusion**

Environmental pollution is one of the biggest problems that are caused by human activities that should be overcome to see a good tomorrow and to provide our descendants a good future and a healthy life. Many environmental concerns are there for communities and around the world to address. One should always remember that pollution problems are continuously affecting all of us; therefore it is our duty to try our best to help and restore ecological balance to this beautiful world which we call a home. One should recognize the major polluters and must protect the air and water at least of that society. Peoples should be encouraged to stop pollution, create awareness of everything about this problem, and make a protest against the local polluters together. The individual is to be educated on the danger of different types of pollution. People should be aware about all consequences and results of the environmental pollution in order to prevent the worst from

happening. So let's move further to protect the water we drink, the air we breathe, and the soil we use to grow our food and all forms of pollution that are dangerous to the environment.

## Polyandry

Anna Szala and Todd K. Shackelford  
Department of Psychology, Oakland University,  
Rochester, MI, USA

## Synonyms

Bigamy; Plural marriage; Polygamous marriage; Polygamy

## Definition

Polyandry is one of the forms of polygamy; in sexually reproducing diploid animals, it is the mating system of females having two or more mates, successively or simultaneously.

## Introduction

Historically, according to Bateman's Principle, it has been argued that polyandry provides no fitness benefits to females (Bateman 1948). However, polyandry occurs frequently in nature and later analyses showed that polyandry may provide benefits for females not only in animals (e.g., Arnqvist and Nilsson 2000; Simmons 2005) but also in humans, in particular. Despite some costs, such as increased predation risk, exposure to diseases, energy and time costs, and physical harm, having multiple mates may be beneficial, because it may secure additional male-provisioned resources to the female and her offspring. In addition, paternal uncertainty may decrease a male's willingness to harm offspring produced by the female and increase the male's investment and paternal care. A notable aspect of polyandry is sperm competition between males, which may select for cryptic female choice to thereby secure genetic diversity or higher-quality genes for offspring.

## Polyandry in Nonhuman Animals

In animals, polyandry refers to a female having two or more mates in a breeding season. Polyandry is common in nature and is more prevalent in animals for which having a low-quality male mate is highly costly (Colegrave et al. 2002). It can be observed in various species, such as bees, crickets, honeybees, frogs, fish, birds, tortoises, whales, polecats and other ferrets, house mice, and marmosets. Polyandry is a feature of social organization among Callitrichidae, a family of New World monkeys. Polyandry in primates is often correlated with reduced or reversed sexual dimorphism, such that females are larger than

males. In wattled jacanas, females copulate with many males, which leads to sperm competition, resulting in the most viable sperm fertilizing the eggs and increasing genetic diversity of the offspring (Emlen et al. 1998). In redback spiders, females store the sperm of several mates and can actively affect the paternity of offspring (Snow and Andrade 2005). In addition, in bank voles, monandrous females' offspring have lower survival rates than polyandrous females' offspring, due in part to the decreased risk of infanticide by males (Klemme and Ylönen 2010). There are, however, species in which polyandry occurs but for which there are not clear benefits to the female. In marine turtles, for example, polyandry appears not to generate benefits for the female, but instead appears to be an incidental consequence of intense male sexual aggression (Lee and Hays 2004).

## Polyandry in Humans

In humans, polyandry has been defined in several ways, including having more than one husband or partner at a time, while the husbands or partners are not married or partnered to any other women. It has been argued that the specific shape of the human penis may serve as an adaptation to remove rival male sperm from the reproductive tract of a polyandrous female (Gordon et al. 2003). One of the most common forms of human polyandry is fraternal (adelphic) polyandry, in which a woman marries two or more brothers. Polyandry is much less frequent than polygyny (one male mated to more than one woman) but has been observed in many societies, including in Africa, Asia, Europe, Oceania, and both Americas. Societies with polyandry are usually small, e.g., Indian societies having from several hundred (Toda people) to approximately 80,000 (Khasi people) members. It has been estimated that there are only several hundred modern societies in which polyandry is commonly practiced, but in none of these places is it officially legal. Many sects of most of the major religions (e.g., Christianity, Judaism, Islam) perceive polyandry as unacceptable. In many small societies around the world, the native culture and traditions were

transformed or eradicated and, therefore, it is difficult to estimate the prevalence of polyandry in the past before these transformations or eradication occurred.

## Polyestrous

John J. Parrish and Joan L. Susko-Parrish  
Department of Animal Sciences, University of  
Wisconsin-Madison, Madison, WI, USA

## Synonyms

[Estrous, oestrous](#); [Estrus, oestrus, heat](#)

## Definition

Estrus – receptive to mating, sexual activity  
Anestrus – not cycling

## Introduction

Estrus or oestrus is the period of time when a female accepts a male for the purpose of mating. In most placental mammals, this is restricted to hours or a few days. The interval until the next expression of estrus is called an estrous (oestrous) cycle. Polyestrous species including cattle (Sartori and Barros [2011](#)), pigs (Senger [2012](#)), elephants (Hildebrandt et al. [2011](#)), domestic and some non-domestic felids (Brown [2011](#)), water buffalo (Perera [2011](#)), and some rodents (Senger [2012](#)) express an estrus period and estrous cycles that repeat throughout the year.

In contrast, seasonally polyestrous species express multiple estrous cycles in only one period of the year depending on environmental factors such as daylight or feed availability. Examples of seasonally polyestrous species are the horse (Aurich [2011](#)), sheep (Bartlewski et al. [2011](#)), wild domestic and some non-domestic felids (Brown [2011](#)), and hamsters (Henningsen et al. [2016](#)). Species that exhibit only a single estrous cycle and do not return to estrus but exhibit anestrus are said to have a monoestrous cycle. This includes species that have just two estrous cycles in a year separated by an extended anestrus periods. Examples of species with monoestrous cycles include the canine and wolf (Concannon

[2011](#)) and bear (Senger [2012](#)). Interestingly, marine mammals of the orders Pinnipedia, Cetacea, Odontoceti, and Sirenia tend to be monoestrous, but a few may have a second estrus cycle within a year or, like the Pinnipedian sea otter, may be polyestrous until pregnancy (Pomeroy [2011](#)). Marine mammals may be functionally monoestrous because males and females migrate to different locations following mating. There are also examples of captive Cetacea such as the bottlenose dolphin being polyestrous or seasonally polyestrous (Pomeroy [2011](#)).

## Length of the Estrous Cycle

The estrous cycle of polyestrous and seasonally polyestrous species varies greatly. The values for various species include (1) 4 days in mice, rats, and hamsters (Senger [2012](#); Henningsen et al. [2016](#)); (2) 17 days in sheep (Bartlewski et al. [2011](#)); (3) 21 days in cattle, horses, pigs, and water buffalo (Perera [2011](#); Sartori and Barros [2011](#); Senger [2012](#)); (4) 21–42 days in captive bottlenose dolphins (Pomeroy [2011](#)); and (6) 91–126 days in the elephant (Hildebrandt et al. [2011](#)). In the felids, most species are induced ovulators, ovulating in response to mating, and have an estrus of a few days to 2 weeks and an interestrus or proestrus period of several weeks that repeats if the female does not become pregnant. The estrous cycle, estrus plus interestrus period, ranges from approximately 14 days in the pallas's cat, 21 days in the domestic cat, 7–21 days in cheetahs, 10–20 days in leopards, 15–40 days in the clouded leopard, and 18–40 days in the tiger (Brown [2011](#)). As monoestrous species cycles do not repeat, a similar comparison is not possible.

## Endocrine Changes of the Polyestrous Cycle

The estrous cycle can be divided by the periods of proestrus, estrus, metestrus, and diestrus. These periods can be seen in relationship to the hormonal changes in Fig. 1. Estrus and the observed

**Polyestrous, Fig. 1** Endocrine changes during an estrous cycle of a polyestrous species. This is an example of the endocrine changes in the bovine. At the top are the ovarian changes with the corpus luteum (CL) undergoing regression to form the corpus albicans (CA). The follicle grows to eventually undergo ovulation and form a new CL. Additional follicles may grow but undergo regression or atresia as indicated by the X through the follicle. In the center are hormonal secretions of the ovary and uterus. The follicle produces estradiol which decreases following

ovulation or regression/atresia. The corpus luteum produces progesterone. Regression of CL is caused by the prostaglandin F<sub>2α</sub> (PGF<sub>2α</sub>) released from the uterus if the female is not pregnant. At the bottom are the changes in the anterior pituitary gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). The FSH triggers development of follicles which are enhanced by LH, and then LH triggers ovulation of a preovulatory follicle (Based on the work of Senger 2012)

receptivity of the female to the male are triggered by an increase in estrogen from follicles on the ovary. The start of estrus is shortly before or after peak estrogen is reached. In some species such as cattle, when males are not available, females will stand to be mounted by other females which indicates the start of the estrus period. In response to the rise in estrogen, gonadotropin-releasing hormone (GnRH) is released from the hypothalamus, which stimulates luteinizing hormone (LH) release from the anterior pituitary. The LH reaches the ovary via the bloodstream, binds to follicular cells, and triggers ovulation of the

follicle. The remnants of the follicle then become the corpus luteum (CL) that releases progesterone or a metabolite of progesterone. In polyestrous species, the corpus luteum regresses if the animal is not pregnant, generally due to release of prostaglandin F<sub>2α</sub> from the uterus. Follicles begin to grow under the influence of follicle-stimulating hormone (FSH), and the estrous cycle is repeated. In a polyestrous species, maternal recognition of pregnancy occurs when a signal from the embryo allows maintenance of the CL and continued progesterone production. This signal can be interferon  $\tau$ , estradiol, or other unidentified

compounds depending on species (Senger 2012). In a pregnant female, progesterone is maintained and estrous cycles stop during pregnancy and lactation as gestational and lactational anestrus.

## The Seasonal Polyestrous Cycle

In seasonally polyestrous species, estrous cycles begin during a particular season of the year. Repeated estrous cycles occur until the female gets pregnant or until an environmental signal causes estrous cycles to stop. In most cases this signal changes in length of darkness (Fig. 2). Species such as sheep become polyestrous in the fall (short-day breeders), but horses become polyestrous in the spring (long-day breeders). Melatonin is released from the pineal gland at night so it is higher during the fall with increasing length of darkness and lower in the spring as the dark period decreases. Melatonin binds to receptors on

hypothalamic RFRP neurons (Henningsen et al. 2016) that in turn release RFRP peptides. In general, RFRP peptides bind to kisspeptin neurons modulating the release of kisspeptin. Kisspeptin in turn binds to receptors on GnRH-releasing neurons to trigger release of GnRH. The response of the melatonin-RFRP systems appears to be similar in both short- and long-day breeders in that with increasing melatonin there is decreasing RFRP. Specific species respond to the changing levels of RFRP peptides differently with the apparent goal to have parturition occur during the most optimal time of the year. Sheep have a gestation of 152 days, while horses have a gestation of 330–345 days. In species such as sheep, in the spring when day length increases, there is decreasing melatonin and decreasing RFRP peptides that inhibit kisspeptin neurons, and hence sheep have low GnRH and do not cycle in the spring. In contrast, in the spring horses exhibit a stimulation of kisspeptin neurons by decreasing

### Long Days (Short Nights)

### Short Days (Long Nights)

**Polyestrous, Fig. 2** Impact of seasonal light changes on seasonal polyestrous species. The figure demonstrates the impacts of light changes on the ewe and mare which differ in the impact of seasonal changes in light. Melatonin which is produced during the dark period of a day is low during the shorter nights of the fall as compared to the longer nights of the spring. Melatonin impacts the RFRP neurons to release RFRP peptides. Up to this point in the sequence, there is no difference in the responses of the mare and ewe. The RFRP peptides impact kisspeptin neurons differently

with increasing RFRP peptides stimulating kisspeptin neurons in the mare but inhibiting them in the ewe. The kisspeptin neurons release the kiss protein that stimulates gonadotropin-releasing hormone (GnRH) neurons to release GnRH and thus stimulate cyclicity. Inhibition of kisspeptin neurons results in low GnRH and anestrus. The opposite effect occurs in the mare and ewe when RFRP peptides decrease (Based on the work of Henningsen et al. 2016)

RFRP peptides. Hence in the spring, horses have increasing GnRH that stimulates estrous cycles that become polyestrous. These effects reverse as melatonin levels change. The entering of polyestrous cycles during the breeding season has been described as similar to initiating puberty and the reverse as the species exits the breeding season (Senger 2012). It should be noted that some species may also be seasonally polyestrous due to availability of food resources. This may be true in species that migrate during gestation to a more appropriate environment for parturition and development of young such as seen in marine mammals like whales (Pomeroy 2011).

## The Monoestrous Cycle

In monoestrous species, the endocrine changes in the pregnant and nonpregnant cycle are similar (Concannon 2011). The initial changes of follicular development, ovulation, formation of the CL, and initial progesterone production are similar to what is observed in the polyestrous species. However, there is no maternal recognition of pregnancy signal, and the CL remains present even if the female does not become pregnant. This leads to these species having pseudopregnancy if they do not become pregnant with the development of the mammary gland and lactation around the time when parturition would normally occur.

## Other Environmental Impacts on the Polyestrous Cycle

Many species experience other environmental impacts on the estrous cycle. For example, water buffalo shows decreased cyclicity during dry periods of the year in tropical countries that have relatively constant photoperiods (Perera 2011). There is a decrease in forage availability during this dry period. Following the arrival of the rainy season and increase growth of forages, water buffalo cyclicity returns. Similar effects are seen in cattle due to decreased feed availability (Sartori and Barros 2011). Temperatures also impact estrous cycles with high temperatures triggering

anestrus as is seen in water buffalo in many of the high-heat regions of India (Perera 2011).

## Conclusion

Polyestrous is the presence of repeated estrous cycles. Seasonal polyestrous species respond to environmental signals so that estrous cycles occur during particular seasons depending on how the RFRP peptides indirectly impact GnRH-releasing neurons of the hypothalamus. The basic hormonal changes of the cycles are similar in terms of follicle development, formation of the CL, and need for maternal recognition of pregnancy. A species with a monoestrous cycle is one in which estrus occurs only once or possibly two times per year. A monoestrous species also differs in that maternal recognition of pregnancy does not occur and the CL produces progesterone or a metabolite regardless of whether the animal is pregnant.

## Polygenic Inheritance

Gavin Vance<sup>1</sup> and Todd K. Shackelford<sup>2</sup>

<sup>1</sup>Oakland University, Rochester, MI, USA

<sup>2</sup>Department of Psychology, Oakland University, Rochester, MI, USA

## Synonyms

Genetic inheritance; Genetic variation; Multiple gene inheritance

## Definition

Polygenic inheritance refers to any phenotypic trait resulting from the combinatorial effects of two or more genes.

A polygene is any gene that interacts with one or more other genes to influence some aspect of phenotypic expression. Physical characteristics such as height, skin color, and eye color in humans are examples of polygenically controlled phenotypes. However, certain phenotypes, such as height and weight, although partially the result of polygenic inheritance, are also influenced by environmental factors. As a result, it can sometimes be difficult to determine the influence of specific genes and environmental factors on phenotypic expressions.

Much of the existing research concerning polygenes comes from the medical field and typically investigates the extent to which diseases and disorders may be the result of multiple, interacting genes. For example, Antoniou and Easton (2003) presented evidence suggesting that identifying multiple genetic loci associated with breast cancer may be useful for determining whether an individual is more susceptible to developing the disease. Additionally, Antoniou and Easton argued that screening methods that focus on family members may be more likely to identify polygenes associated with breast cancer compared to methods that merely screen the general population.

Other researchers have also detailed the potential benefits of using polygenic information in concert with risk factors for diseases such as age and family history to improve screening procedures (Chowdhury et al. 2013). Specifically, Chowdhury and colleagues noted the potential for polygenic information to inform stratified screening methods, wherein particular demographics within the general population can be identified as high risk for diseases like prostate and breast cancers. However, the researchers contrasted these potential benefits with the risk of failing to identify high-risk populations and subsequently excluding or overlooking these groups during screening procedures.

Khoury et al. (2013) expand on the ideas discussed by Chowdhury et al. (2013), suggesting that, although scientific advances in genome sequencing may enhance the ability to detect monogenic diseases, the capability of this technology to detect polygenic diseases will be comparatively weaker. As a result, Khoury et al. advise caution when considering the use of polygenes to inform stratified screening procedures, especially when these threaten to supplant well-established screening procedures.

Although much of the literature on polygenic inheritance concerns disease in humans, there has been at least some research investigating the polygenic inheritance of behavioral traits in nonhuman animals. In particular, Shaw (1996) provided evidence that genes at several different loci influence differences in songs produced by male crickets. Shaw's research implies that the influence of polygenes is not limited to physical characteristics or disease. Furthermore, research investigating the polygenic inheritance of Tourette's syndrome similarly implies that polygenes affect behavioral traits in humans (Comings et al. 1996).

The existing literature regarding polygenic inheritance, although informative from a medical perspective, is somewhat limited in scope. At this point, there has been little investigation of polygenic influences of behavior in nonhuman animals and few investigations regarding human behavior. These areas are open for future empirical investigation, and indeed, a great deal more research is needed to better understand whether and how various behaviors may be influenced by multiple genes.

## Definition

Polygenes belong to a group of nonepistatic genes that affect a phenotypic trait by the combined action of numerous similar genes.

## Introduction

A polygene or “multiple gene inheritance” can be defined as a group of nonepistatic genes that act together to influence a phenotypic trait. Traits controlled by polygenes are called polygenic traits, and they display continuous variation in

phenotype. The variation or phenotypic combinations of these traits can be increased by increasing the number of genes. These are quantitative traits, for example, the visible characters like skin color, eyes, height and weight, fingerprint pattern, bristle number, and wing morphology (Mackay 1996). There are nonvisible traits like blood- pressure, intelligence, autism, and longevity. There are adult-onset diseases like Diabetes Mellitus, cancer, glaucoma, hypertension, ischemic heart disease, bipolar disorder, schizophrenia, psoriasis, thyroid diseases, and Alzheimer's disease that are controlled by multiple genes. In the case of skin color, which is governed by numerous genes and two alleles for each gene where one is responsible for pigmentation while other is not, and hence there are so many combinations in skin color (Barsh 2003). Several diseases that have genetic causes in them are polygenic like cancer, diabetes, and numerous others. The frequency of the phenotypes of polygenic traits and pattern of polygenic inheritance follows a bell-shaped curve, which is obtained when the values of polygenic traits are plotted with the mode representing the fit individuals. These traits are influenced by the interaction of a single gene or multiple genes and are controlled by both environment and genes and hence called multifactorial that depends on the interaction of both. The variation in these multifactorial traits also depends on the changeable level of interaction between gene and environment (Complex Trait Consortium 2003). Examples of diseases considered to be the results of many contributing factors are cleft palate, congenital dislocation of the hip, congenital heart defects, neural tube defects, pyloric stenosis, talipes.

Polygenic locus, which is called quantitative trait locus (QTL), is defined as the locus where one or multiple genes are found on the chromosome, and their different allelic substitutions lead to the variation in the quantitative character (Lerner 1968). A mutation that is recessive for a disease but is expressed phenotypically, both the alleles have to be recessive. Similarly, in any polygenic disease, there are more than two alleles, and if anyone of them is normal, then in such a case, the disease cannot be expressed and resemble a normal or Gaussian distribution.

## Mapping of Polygenes

Polygenes are mapped by a technique called QTL mapping. In this procedure, the locus where the genes are present is investigated with the help of other marker genes that belong to traits that are interrelated with that polygenic trait. It is mapped by identifying the molecular markers like SNPs or AFLPS that have the maximum correlation with any observed trait. Sometimes when the genome of an organism is unknown, then the genes of the same function are searched in another organism with known genome, and they are aligned and matched with the help of tools such as BLAST. These genes are then further sequenced and studied to know the degree of change in sequences with the change in the underlying phenotype (Watanabe et al. 2009). The number of loci and their interaction, along with the complexity of genetic architecture affecting the polygenic phenotype, is studied. This can help in knowing how the phenotype is evolving. QTL also helps in knowing about how many genes are involved and the level of expressivity and penetrance of the trait.

QTL mapping is done by the following methods.

- (a) ANOVA: The simplest method to calculate QTL is the application of ANOVA (analysis of variance).
- (b) Interval mapping: Interval mapping technique was first introduced by Lander and Botstein (1989). In it, QTL locus is assumed to be present between the markers that lie in a genetic map.
- (c) Composite interval mapping (CIM): In this type of mapping, various linked markers are taken as covariates for QTL analyses.
- (d) Family-pedigree based mapping: It involves searching genes for the polygenic trait in the organism by analyzing its similarity from other genomes of its own family or related families (Jannink et al. 2001).
- (e) Association studies: Single nucleotide polymorphism (SNP) can be used to link polygenes with the multifactorial trait. They can also reveal the connection between two populations on a disease-causing gene (Gibson and Muse 2009).

## Polygenic Inheritance

Its inheritance is called polygenic inheritance or quantitative inheritance, and it doesn't follow discontinuous variation like Mendelian inheritance, for example, height in pea plant, which is present in two extreme varieties, short and tall. Polygenic traits instead follow continuous variation like human height, that is, it is found in numerous forms. Polygenic genes control both metric and meristic traits.

In polygeny, traits displayed are neither dominant nor recessive where one allele's function does not hinder the effect of another allele as in the case observed in Mendelian genetics, but it exhibits incomplete dominance, and therefore all the alleles contribute in the phenotype by additive effect where different allelic interactions create variation in polygenic traits.

The probability of a progeny to acquire polygenic characteristics from parents cannot be determined by Punnett's square because the total number of genes involved in any polygenic trait is complicated to mark out. It can be determined by the normal distribution of probabilities where offspring displays intermediate phenotype of the trait possessed by the two parents.

## Polygynandry

Anna Szala and Todd K. Shackelford  
Department of Psychology, Oakland University,  
Rochester, MI, USA

## Synonyms

[Bigamy](#); [Plural marriage](#); [Polygamy](#)

## Definition

Polygynandry is a form of polygamy; in sexually reproducing animals, it is a multi-male and multi-female mating system. Polygynandry encapsulates both polygyny (males having multiple female mates) and polyandry (females having multiple male mates) within the same species.

P

## Introduction

Sexual promiscuity in the form of polygynandry may provide benefits for both females and males. However, the types of benefits females and males gain are different due to differences between the sexes; males have the potential to produce a much higher number of offspring compared to females. Therefore, females more than males typically express quality-based mate preferences and males more than females typically express quantity-based mate preferences. For example, because of sperm competition, females can increase genetic diversity and quality in their offspring and introduce cryptic female choice by mating with multiple males in a sufficiently brief

time period. In addition, having multiple mates may secure additional resources for the female and, due to paternal uncertainty, decrease male infanticide or willingness to harm an offspring and increase their investment and paternal care. In males, fitness is directly increased with multiple female mates because males can fertilize the egg(s) of multiple females and, therefore, increase the number of offspring they produce.

## Polygynandry in Nature

In animals, polygynandry refers to two or more females or males having two or more mates in a breeding season. Polygynandry is common in nature; it can be observed in various species, including cichlid fish, dusky pipefish, European badgers, red foxes, territorial frogs, alpine accentors, sea spiders, collared pikas, and African ground squirrels. In the case of females, the benefits of multiple mating can include increasing the number of offspring produced. Multiple mating partners also may contribute materially to the well-being and safety of offspring, as in Galapagos hawks, dunlocks, and dark-eyed juncos. Multiple mating by females decreases the risk associated with mating with a male with an insufficient quantity or quality of sperm, which decreases the risk of producing unfertilized eggs, e.g., in dark-eyed juncos, in which a female's social partner often has lower genetic quality than the quality of other possible mates (Bellamy and Pomiankowski 2011; Davies et al. 2012). According to Fisher's (1930) sexy son hypothesis, multiple mating by females increases the chances of producing a greater quantity of sons that inherit their father's sexual attractiveness, which could then increase the son's attractiveness as a mate. This appears to occur, for example, in songbirds in which mated females seek extra-pair copulatory partners with more colorful plumage than their social partner. In addition, more colorful plumage and longer tail predict survivability of males. In the case of males, as in fruit flies, reproductive success increases with the number of copulations with different females. Also, if multiple males share paternity in offspring produced by the

same female, a given male may benefit by abandoning the female to search for additional mates (Davies et al. 2012). In humans, polygynandry may refer to a male or female being married or involved in a relationship with more than one male and with more than one female. Polygynandry in humans is relatively rare. One example of polygynandry occurs in peoples of the Indian Himalayas, who mix polyandry and polygyny to thereby form a polygynandry-like social and mating structure (Levine and Silk 1997).

## Polygyny

Indu Bhatt  
Department of Biotechnology, IMS Engineering College, Ghaziabad, Uttar Pradesh, India

## Definition

A pattern of mating in which the male has more than one female mate.

## Introduction

Darwin theory of organic evolution suggests two forms of mechanisms for evolution: natural selection, wherein a species adapts to its biotic and abiotic environment, and sexual selection which is based upon competition to find the mate. Mating systems describe who mates whom and are dependent upon spatial and time constraints, need of parental care, and genetic compatibility (Kvarnemo 2018). It is classified on the basis of the number of mates acquired by an individual species in a breeding season. In the monogamous mating system, one male mates with one female at a time and is usually prominent in the species in which both the male and female contribute to defend and raise the young or in which males have limited chance of mating more than one female. Polygamous mating system, on the other hand, is either polyandrous (one female mates with more than one male) or polygynous (one male mates with more than one female).

## Polygyny

When one male mates with multiple females, it is termed as polygyny. It is most commonly seen in mammals and is also present in few birds and insects. The system is primarily based on male-male competition for mating a female and helps in increasing their reproductive fitness. It is common in the species where females provide most of the parental care and males offer little or no role in it.

## Resource Defense Polygyny

Its prominent feature is territorial defense by an adult male. It occurs when female groups are attracted to a resource and males defend it and compete for gaining territorial possession (Beletsky and Orians 1994). The territories defended by males have resources required for

successful mating (McCracken and Bradbury 1981), for example, black-winged damselflies males defend a territory containing the aquatic vegetation appropriate for laying eggs and wait for females to come to them.

## Female Defense Polygyny

It is displayed by a harem that is defined as an animal group constituted by a dominant male and a group of females and their offspring. The dominant male mates with the sexually active females in the group and provides them defense. As the juvenile males mature, they leave the harem. The females maturing sexually may continue to be a part of the same harem or move to other.

## Lek Polygyny

This polygyny is displayed by a number of species of insects, birds, and mammals. A lek is defined as an aggregation of males in a location that is not associated with resources. Usually the aggregation is formed in an area that has a significant number of sexually active females or where such females are likely to visit. The group of males attract the females by displaying their sexual features. Females choose the male for copulating and usually don't form lasting association with them. The males provide no parental care to the offspring. Leks are preferred as they provide the choice of finding a mate with better characteristics and at a reduced effort (Kokko 1997).

## Scramble Competition Polygyny

This polygyny is characterized by a competition in mating opportunity by locating females and found in many insects, spiders, and few mammals like squirrel. The mating success is dependent on the repeated location of the

mates, and hence, in addition to social dominance, time management and spatial memory also play a pivotal role in this mating system (Foley et al. 2018). More mobile males show a better success in mating as mobility increases the chance of finding the female mates (Muniz et al. 2018).

[The polygamy threshold model](#)

## Definition

The polygyny threshold model is a framework proposed to describe optimal female mate choice in resource defense polygyny systems. The polygyny threshold is defined as the increase in breeding resources required to offset costs of sharing a territory with another female.

## Introduction

Until the 1960s, polygyny was largely considered a result of an excess of female to male breeders (Searcy and Yasukawa 1989). This explanation was found inadequate as it became clear that it is fairly common to see territorial males remaining unmated despite courtship efforts, while neighboring males mate polygynously. In the mid-1960s, the polygyny threshold model (hereafter the PTM) was proposed as an adaptive explanation to this phenomenon (Orians 1969; Verner 1964; Verner and Willson 1966).

Since its inception, the PTM has been applied on a wide range of organisms that exhibit social resource defense polygamy, including birds, mammals, fishes, reptiles, amphibians, and invertebrates. The threshold mechanism in the PTM is identical for polyandrous and polygynous systems, so the “Polygamy Threshold Model” would be a more appropriate term (Gowaty 1981), but because the model initially was proposed for polygynous birds, and because social polygyny is far more common than social

polyandry, the term “Polygyny Threshold Model” has been most widely used.

## How the PTM Works

The PTM describes the mating pattern in resource defense polygyny systems. Unlike in lek polygyny, female defense polygyny, and scramble polygyny, males in resource defense polygyny systems provide breeding resources to the female and offspring. They defend breeding territories which often hold food or other valuable resources, and they often take part in parental activities like food provisioning, incubation, and defense against predators. The breeding territories are typically aggregated in clusters, and females have the opportunity to evaluate several males before making their mate choice.

In the PTM the breeding resources offered by individual males are thought to vary, and to maximize reproductive success (i.e., number of offspring raised), a female should settle with the male breeder that offers the most. Male breeding resources are typically finite (e.g., food resources on the territory, or time spent by male incubating or feeding young), and monogamous females may take advantage of all resources the male offers. Females in polygynous dyads, however, have to share the breeding resources and experience sharing costs in the form of loss of breeding resources to the other female. Therefore, when a female considers settling as a secondary female, she should subtract the expected sharing costs from the overall resources offered by the male. If she finds that the territory still yields more breeding resources than available bachelor-held territories, the polygyny threshold is exceeded and she should prefer polygyny over monogamy (Orians 1969; Verner 1964; Verner and Willson 1966). All females that settle in a breeding cluster are expected to make this calculation for the available breeding territories before making their mate choice, and female settlement should follow an ideal free distribution with the most resourceful males becoming polygynous and

the poorest males either having to settle for monogamy or remaining unmated.

Early variants of the PTM used aspects of territory quality (denoted as environmental quality in Fig. 1) as predictors of female mate choice. In time, it became clear that offspring survival was also affected by male parental effort and male skills (e.g., breeding experience, competitive skills, foraging skills, and skills and resolve to defend against predators) (Davies et al. 2012; Webster 1991). Male attractiveness was also proposed to be a genetic trait that the offspring might benefit from inheriting (Weatherhead and Robertson 1979). This identified the problem of how to decide on which traits mate-prospecting females find most valuable and base their mate choice on – male characteristics, territory characteristics, or a mix of both. Territory quality (or environmental quality) was therefore substituted with the term male “Breeding Situation Quality” (BSQ), which represents the sum of resources offered by males that affect the breeding outcome, and ultimately the reproductive fitness of females (Wittenberger 1981). Instead of trying to pinpoint which cues females use to choose a mate, the assumption is then made that females choose the best males available at the time of their settlement. The first chosen male in a breeding cluster is considered to have the highest BSQ, BSQ then declines over the colonization order, and males that are chosen last or remain unmated are assigned the lowest BSQ (Searcy and Yasukawa 1989).

## Assumptions of the PTM

The PTM rests on the following assumptions:

- Females experience costs associated with sharing a mate.
- There is variation in male BSQ across the breeding population.
- Females can accurately assess BSQ of the males in the system.
- Females value BSQ on a similar scale.
- Females prefer breeding territories that offer the highest amount of BSQ.

**Polygyny Threshold Model, Fig. 1** A graphical representation of the PTM modified from Orians (1969). The *upper diagonal line* gives the expected reproductive success for a monogamous female and the *lower line* for bigamous females. The *dotted lines* denote the environmental quality or Breeding Situation Quality (BSQ) of territories (a) and (b). The *vertical short-dashed line* between the diagonals indicates the sharing costs for bigamous females on the best territory (b) in terms of reduced

reproductive success. The *horizontal long-dashed line* between the diagonals indicates the increase in BSQ needed to offset these costs, i.e., the polygyny threshold. As the threshold balances the costs of sharing, the monogamous female on territory (a) has equal prospects of reproductive success to a bigamous female on territory (b). A larger difference in BSQ favors bigamy, and a smaller difference favors monogamy

- Females are equal in quality and distribute according to offered BSQ in an ideally free fashion (i.e., after settlement, the number of breeders on the territories is proportional to the amount of resources available on the territories).

A critical requirement for the PTM is that females experience a cost associated with sharing a territory with another female breeder. If not, no threshold needs to be compensated and other mechanisms may better explain the dynamics of the mating system (Pribil 2000; Searcy and Yasukawa 1989).

### Predictions Derived from the PTM

A number of predictions may be derived from the PTM, but some of the main ones are related to settlement order, reproductive success for females, and male attractiveness.

**Settlement order:** Using the settlement order as a proxy for BSQ, the first settled territories should have highest BSQ and reach polygynous status first, and:

- Primary polygynous females should precede monogamous females in the settlement order.
- There should be a positive correlation between BSQ and harem size.

**Reproductive success:** If secondary females are compensated for costs associated with sharing a breeding territory, they should on average have access to as much BSQ as simultaneously settling monogamous females, and:

- Secondary females should have similar reproductive success to contemporary monogamous breeders.

**Male attractiveness:** Using harem size as a female preference criterion, polygynous males should be preferred as genetic sires over monogamous males:

- The proportion of genetic paternity loss should be lower for polygynous males than for monogamous males.

## Tests of the PTM Predictions

Species-specific life-history constraints and varying ecological factors have shaped variants of resource defense polygyny which to some extent differ in cost–benefit trade-offs, and over the years modifications have been made to the PTM to tailor it to specific variants (Andersson 1994; Davies et al. 2012; Garson et al. 1981; Grønstøl et al. 2003; Leonard 1990; Searcy and Yasukawa 1989; Slagsvold and Lifjeld 1994). Since the 1960s, numerous studies have tested the predictions of the PTM listed above, and the overall conclusions are: (1) harem size does not overall correlate with settlement order, (2) monogamous females tend to breed earlier in the settlement order than predicted by the PTM, (3) monogamous females perform on average better than secondary females in terms of offspring production, and (4) polygynous males do not suffer less cuckoldry than monogamous males. All of these conclusions are contrary to expectations from the PTM.

There have been many suggestions for how to explain the lacking empirical support of the PTM predictions. These include sexy-son effects, i.e., that reproductive fitness benefits of polygyny may be genetic and manifested as quality rather than quantity of offspring, an excess of breeding females to breeding males, and maladaptive female choice because (1) males deceive females into believing that they are unmated, (2) mate sampling may be costly and the opportunities to engage in mate sampling may be restricted, or (3) the environment is unpredictable and females may be unable to foresee unfortunate changes that may occur after they have made their mate choice. Although some of these explanations may be relevant in some mating populations, neither of them seems likely to provide a general explanation for why predictions are not met (Davies 1989; Grønstøl et al. 2003).

## Revisiting the PTM Assumptions

So, empirical results indicate that the PTM does not accurately describe the settlement dynamics in resource defense polygyny systems. For instance, empirical results place monogamous females earlier in the breeding order than expected. Why so? After all it seems reasonable to assume that the earliest female settlers choose the best available males, and that subsequent settlers also consider these as premium territories, resulting in these earliest settled territories becoming polygynous. Could it be that some early settling females remain monogamous because it is in their interest to do so, and that they are able to enforce monogamy by denying access for subsequent female mate prospectors despite male courtship attempts?

Common for most studies modeling variants of the PTM is the underlying assumption that females are equally resourceful and introduced sequentially to choose a mate in a system with a seasonal decline in reproductive success, in a manner conforming to the ideal free distribution. If females settle with mates in an ideally free fashion, it should in essence be a zero-sum game for the females, but what if it is not? When PTM was proposed and onwards for quite some time, research on mate choice and sexual selection was very much focused on variation in male quality and in the expression of male sexual ornaments considered attractive by females. Female traits and strategies to influence the mating outcome was not so much the focus of attention (Rosenqvist and Berglund 1992). Since then, however, a bulk of studies have shown that females differ individually, much like males do, and that females act in their own interests to maximize their reproductive fitness. This gives reason to question the validity of the equal-female assumption.

## Sexual Conflict and the PTM

What are the female interests in resource defense polygyny? When there is a cost associated with sharing a male, resident females experience a reduction in BSQ with the addition of a secondary

female on the territory. This should motivate resident females to oppose polygyny and try to enforce monogamy. Males, however, are likely to increase the number of offspring they produce if able to attract more mates, so they should strive for polygyny. This highlights a sexual conflict – a conflict of interests between the male and female in a pair-bond over how males should allocate their breeding resources (Davies 1989; Davies et al. 2012; Parker 1979; Trivers 1972).

Some authors realized decades ago that the PTM did not accommodate this sexual conflict. In one of their papers on Dunnocks (*Prunella modularis*), Davies and Houston (1986) commented that: “there is a more general reason for why the [polygyny threshold] model is likely to fail in predicting observed mating systems – namely, it largely ignores conflicts of interests between individuals,” and Krebs and Davies (1993) stated in their textbook on Behavioral Ecology that “The assumptions of the PTM are like those of ‘the ideal free distribution’” . . . [and] . . . “that ideal free conditions rarely hold in nature because dominant individuals attempt to grab more than their fair share of resources.”

### **Division of BSQ on Polygynous Territories**

The original PTM assumes that females sharing a polygynous territory divide the BSQ evenly. This is probably not the case because BSQ appears to be economically defendable units that females compete over (Emlen and Oring 1977). It has been pointed out that different rules for sharing costs between primary and secondary female will yield different PTM-predictions (e.g., secondary females bearing 50% of the sharing costs vs. being forced to bear up to 100% of the costs) (Altmann et al. 1977; Davies 1989). Several factors are likely to contribute to a nonequal sharing of BSQ.

### **Individual Differences in Female Competitive Strength**

It is quite common to see resident females behaving aggressively towards secondary mate prospectors, and many studies have found that females vary in

competitive strength. It seems reasonable to interpret this aggression as attempts to monopolize their male, or to gain more than their fair share of the BSQ (Davies 1989; Slagsvold and Lifjeld 1994; Wittenberger and Tilson 1980).

### **Degree of Synchrony Between Females in Polygynous Dyads**

The competition over the BSQ increases with increasing temporal overlap between the primary and secondary female (Leonard 1990; Slagsvold and Lifjeld 1994). Birds in general seem to have a reproductive fitness premium on breeding early (Perrins 1970), and the optimal timing of breeding is probably determined by a trade-off between costs and reproductive benefits of early breeding. Individuals able to handle the adverse effects of weather and sparse food early in the season generally do better than individuals that breed late. The optimal time of breeding onset is likely to be condition-dependent, and superior individuals may have earlier optima than poorer individuals (Drent and Daan 1980). The early breeders thus enjoy first pick of territory and take advantage of a longer chick growth season, whereas later breeders do the best of a bad job breeding as early as their condition permits. If prospects of reproductive success had not diminished with delayed breeding, secondary females would probably benefit from breeding later relatively to primary females, which would minimize the temporal overlap. But, as it is, females prospecting for secondary mating status probably cannot afford to delay their breeding to reduce the overlap.

### **Division of Paternal Effort Between the Primary and Secondary Female**

In passerine birds, polygynous males often invest more paternal effort in the brood of the primary female than in the brood of the secondary female, and the extent of this inequality often increases with increased asynchrony between primary and secondary females (Slagsvold and Lifjeld 1994; Webster 1991). There are, however, examples of later breeding secondary females not being disfavored by males. It seems sound to assume that males should allocate their paternal effort in a manner that maximizes the return per unit

invested. If early chicks have higher reproductive value and count as greater (reproductive fitness) losses than later chicks, the polygynous males might do best prioritizing their primary female. However, if the male could rely on a resourceful primary female to raise the offspring reasonably successfully without assistance, whereas a less resourceful, less experienced secondary female would face a larger risk of failure without male assistance, the male would probably raise more offspring if contributing more help to his secondary female than to his primary female (Grønstøl 2003). The more paternal care a resident female stands to lose to a secondary female, the higher her motivation should be to try to monopolize the BSQ and behave aggressively towards female mate prospectors.

#### **Male Interference to Mitigate Female Attempts at Monopolizing Breeding Resources**

In cases where resident females attack females prospecting for secondary mating status, males are sometimes seen to attack the aggressor in what looks like efforts to dissuade the resident females from chasing away the newcomers. This behavior has by several researchers been interpreted as male efforts to facilitate settlement of the female mate prospector. If the prospector is able to settle as a secondary female, recurrent skirmishes may occur with the primary females attacking the secondary females in what gives the impression of being attempts to monopolize as much BSQ as possible. How successful males are in facilitating settlement of secondary females probably depends on their strength and tenacity compared to that of their resident females. Females are sometimes successful in enforcing their interests, whereas the males' interests prevail at other times (Davies et al. 2012).

#### **Incorporating Varying Female Competitive Strength in the PTM**

It seems plausible that ability to monopolize BSQ correlates with female competitive strength. It also seems reasonable to expect female

competitive strength to vary individually in a breeding cluster. Therefore, in order to portray the polygynous settlement as accurately as possible, female despotism should be included when modeling resource defense polygyny. Introducing variation in female competitive strength to the PTM requires a revision of the assumptions. One might keep four of the original assumptions:

- Females experience costs of sharing a mate.
- Females can accurately assess BSQ of the males in the system.
- Females value BSQ on a similar scale.
- Females prefer breeding territories that offer the highest amount of BSQ.

And add some new assumptions:

- Females differ in competitive strength.
- Females can assess the competitive strength of other females relative to their own.
- Females benefit from nesting as early as their condition permits.
- Competitive strength decreases from first to last settled female.
- Strong females monopolize resources at the cost of weaker females to a degree determined by the relative difference in competitive strength between the female antagonists.

Running this framework in a simulation where individual differences in female competitive strength are set to approximately match BSQ-differences between males produces a settlement pattern where some of the early females remain monogamous due to successful deterrence of mate prospectors (Grønstøl et al. 2003). From the simulation results, the following can be extracted: (1) harem size does not correlate with settlement order; (2) the settlement order of monogamous females is similar to that of primary females, and monogamous females settle earlier than secondary females; (3) in terms of reproductive success, monogamous females perform equally as well as primary females and better than secondary females; and (4) because some monogamous males are among the earliest breeders, polygynous males should not (by default) be considered more

attractive than monogamous males. All these new predictions match previous empirical findings well: (1) field studies show that monogamous females are found earlier in the settlement order than expected from the original PTM; (2) overall, studies have failed to document that settlement order significantly predicts harem size; (3) monogamous females are in general found to have higher reproductive success than secondary females, instead of similar success which is predicted by the original PTM; and (4) paternity studies reveal that polygynous males are not cuckolded less than monogamous males, which they should according to the original PTM.

## Concluding Remarks

The new predictions generated from a PTM-model that incorporates a variation in female competitive strength match the accumulated empirical results well (Grønstøl et al. 2003), which strengthens the hypothesis that strong females may be able to impose their own interests in the sexual conflict over parental care by enforcing monogamy and monopolizing the breeding resources of their mate.

The simulation results placed monogamous males at both the high and the low end of the BSQ scale. This implies that it is not appropriate to use harem size as a proxy for male attractiveness (or BSQ) in resource defense polygyny systems without accompanying evidence demonstrating that such a link between harem size and male quality does exist. One might speculate that some of the most attractive males perhaps may do better breeding monogamously if they are confident that they will be preferred as extra-pair sires by neighboring females. They would then parasitize the parental effort of neighboring males instead of splitting their own parental care over more females (i.e., a strategy of social monogamy and genetic polygyny for the most attractive males). This might even cause these males to be less resistant to social monogamy and easier to monopolize by their (strong) females.

In natural systems of resource defense polygyny there probably exist additional variables that

play a part in the shaping of polygynous settlement patterns, which so far have not been included in the testing framework. An interesting effect that may alleviate sharing costs (and thereby reduce the polygyny threshold) is relatedness between female breeders that share a territory. If females on a polygynous territory are related, costs associated with sharing a territory may be lessened by indirect reproductive fitness benefits of kin selection, i.e., helping a relative to reproduce returns a reproductive fitness gain proportional to the relatedness (also termed inclusive fitness) (Hamilton 1964). Benefits from mutualistic behavior (or reciprocal helping), such as communal defense, may then increase and the resistance to sharing a territory should be lower than for unrelated females (Grønstøl et al. 2015).

An assumption that all variants of the PTM share is that females agree on how attractive the available males are, and that all females, given the chance, would choose the same male. This assumption might to some extent be challenged by research done on mate choice of complementary genotypes. Results have been presented indicating that females in some species prefer to mate with males with a MHC-genotype that is different from, or complementary to, their own MHC-genotype. This is thought to increase the heterogeneity of MHC in the offspring, which should increase the efficiency of the immune system (Mays and Hill 2004). As females are expected to vary with regard to MHC-genotypes, this effect would introduce an element of disagreement over which males are considered the most attractive. The strength of this objection will depend on how well the males' attractiveness as social mates correlates with their attractiveness as genetic sires. Females might prefer to form social bonds with males that offer the most BSQ and covertly seek out more MHC-compatible males as extra-pair mates. Future research will probably establish how strong the effect of selection for complementary genotypes is compared to the preference for male traits that females agree on.

Theoretical models are not better than the foundation they rest on, and it is necessary to revisit, identify, evaluate, and explicitly state assumptions

when applying them to natural systems. New insights might call for corresponding revisions of the PTM.

## Synonyms

Genetic polymorphism; Genetic variation

## Definition

Polymorphism in biology refers to the discontinuous genetic variations leading to the existence of two or more forms, stages, or phenotypes existing in the same species within the same population.

## Introduction

The literal meaning of “Polymorphic” is “having multiple forms.” In biology, the word “polymorphic” is generally used in terms of genes. A gene

is referred to as polymorphic if more than one allele is present at a specific locus of the gene. Furthermore, for being considered polymorphic, each allele must occur in the population at a minimum of 1%. This phenomenon of occurrence is called polymorphism.

Polymorphism can be subcategorized into two basic types, that is, sexual dimorphism and allelic polymorphism. Sexual dimorphism is when the male and female of a species differ physically or phenotypically like humans, whereas the allelic polymorphism denotes the presence of alternate forms of a gene governing a specific trait.

Owing to the presence of two or more allelic variants, different phenotypes are visible, for instance, flower color. An exciting aspect of polymorphism is that it can be seen in any trait, be it morphological, physiological, or behavioral and that too involving any coding or non-coding segment of DNA (nucleus, chloroplast, or mitochondrion) (<https://www.britannica.com/science/polymorphism-biology>).

## Sources and Effects of Polymorphism

Genetic variations or polymorphism owe their existence to the process of mutations. Mutations occur at different rates in different parts of the genome ranging from  $10^{-7}$  to  $10^{-10}$  nucleotide base per generation (Wright 2001). In addition to this, crossing over, which leads to exchange of the chromosomal segments between non-sister chromatids, also contributes to the genetic diversity (NHGRI 2020).

According to the theory of evolution, evolutionary processes lead to polymorphism. In natural conditions, polymorphism is very common. It not only increases biodiversity but is also linked to the adaptability of an organism.

## Common Misconceptions

There are some general misconceptions associated with the word polymorphism. This term cannot be used for character traits that show continuous variation, such as height, although this may be a heritable aspect. Additionally, this

term is also incorrectly used for the description of different geographical races or variants. Still, polymorphism points out that the alternate forms of a single gene must inhabit the same habitat at the same time (Phillips 2020).

Some examples of polymorphism have been provided here:

### 1. Blood Group

The ABO blood group system exhibits genetic polymorphism. People around the world exhibit different blood group phenotypes A, B, AB, and O. These phenotypes are governed by various forms of a gene, that is, alleles present at a single locus. These different phenotypes never get eliminated by natural selection forces because individuals of a particular blood group would be more susceptible to a distinct disease while remaining less susceptible to the others than individuals with a different blood group (Crow 1993; Meade and Earickson 2005).

### 2. Sickle-Cell Anemia

Sickle-cell anemia is a genetic defect occurring due to the single nucleotide polymorphism, where at the sixth position of the  $\beta$ -globin gene, GAG (Glutamic acid) changes to GTG (Valine). The sickle-celled hemoglobin gene is displayed as HbS in contrast to the normal hemoglobin gene HbA. Under low oxygen conditions, the RBCs change their shapes to sickle, which causes great difficulty in transporting oxygen throughout the body. Additionally, the homozygous recessive condition has a short life expectancy, whereas the homozygous dominant and heterozygous conditions are normal, with the latter suffering from a few problems periodically. It is also essential to know that the heterozygous condition has resistance against the malarial parasite. This denotes genetic polymorphism balanced between the fierce selection against the homozygous recessive patients and selection against the homozygous dominant patients by malaria (Wang et al. 2016).

### 3. Plumage Color in Birds

The pattern, color, and arrangements of the layer of feathers that covers a bird are called its

plumage. A large amount of genetic variations can be seen in the plumage of the birds of same species and subspecies.

In a study conducted by Galeotti and coworkers, birds of different species showing intraspecific variation were studied, and it was observed that among the 334 species of the birds studied Strigiformes, Ciconiiformes, Cuculiformes, and Galliformes showed the highest polymorphism. The study suggested that the color polymorphism was a result of evolution under selective pressures (disruptive selection) with respect to the detectability of the bird (Galeotti et al. 2003).

### 4. Styler Polymorphism in Angiosperms

An important example in case of plants is the styler polymorphism in angiosperms. There are four major classes of styler polymorphism in angiosperms: stigma-height dimorphism, distyly and tristyly, the heterostylous conditions, and enantiostyly. The polymorphism exhibited differs in both the relative position of the sexual organisms and the number of floral morphs occurring within the populations (Barrett et al. 2000).

### 5. Major Histocompatibility Complex

The genes governing the major histocompatibility complex are highly polymorphic, which leads to defense against the pathogens (MHC Sequencing Consortium 1999).

Apart from these, there are many examples of polymorphism, like the genes of glucose-6-phosphate dehydrogenase (Verrelli et al. 2002) and genes involved in human taste polymorphism (Fisher et al. 1939). Polymorphism is also depicted in other organisms apart from humans like hoverflies, drosophila, ants, birds, lizards, fishes, plants, etc.

## Conclusion

Polymorphism means discontinuous genetic variations that lead to several different forms/types of members belonging to the same species. It allows the species to adapt flexibility in the environment. Additionally, this provides the space for natural selection, which will eventually lead

to the change in allele frequencies and then microevolution.

## Synonyms

[Heterospecific group](#); [Interspecific group](#); [Mixed species group](#)

## Definition

A temporary or permanent social group consisting of two or more different interacting species in close proximity.

## Introduction

Polyspecific associations, in which two or more species occupy the same space, were noted early on by prolific naturalists like Alfred Russel Wallace (1869) and Henry Walter Bates (1864) in

their descriptions of the mixed flocks of tropical birds in Malaysia and the Amazon (Morse 1977). Since then, nonrandom polyspecific associations have been documented in numerous taxa. It is generally accepted that mixed species groups benefit constituent animals in two primary ways: through predator avoidance and foraging benefits. Mixed species groups therefore aim to achieve an optimal balance between foraging efficiency, given intragroup resource competition, and anti-predator benefits.

### Anti-Predator Benefits

Polyspecific associations provide distinct advantages for avoiding predators, mainly because large group size is an adaptation to predation pressure. There are five mechanisms by which mixed species groups help constituents avoid predation, all of which rely on large group size: the dilution effect, the confusion effect, the selfish herd effect, increased eyes and ears, and defense against predators (Stensland et al. 2003). The dilution effect poses that the likelihood of being attacked decreases with increasing group size. This effect is closely related to the selfish herd effect, in which “selfish” group members (generally more dominant animals) occupy the most central positions in the herd, leaving peripheral members vulnerable to predation. Being in a larger group also confers the advantage of increasing the absolute amount of vigilant eyes and ears. The confusion effect describes the phenomenon in which predators are less successful in capturing individual prey as group size increases (Stensland et al. 2003). All of these mechanisms operate to varying degrees depending on the ecological circumstances in which the mixed species groups form.

Perhaps the most iconic example of polyspecific association as an adaptation to heavy predation is the congregation of ungulate species on the African savannah, in which all of the mechanisms above operate. It has been shown that Thomson’s and Grant’s gazelles (*Gazella thomsoni*; *Gazella granti*) on the Serengeti were less vulnerable to predation by cheetahs (*Acinonyx jubatus*) when in mixed species groups

relative to smaller, conspecific groups. The gazelles shared responsibility for vigilance, thus increasing individual feeding time, providing a significant foraging benefit to individuals in the herd. Cheetahs were detected earlier, and cheetah attacks were less successful and less frequent in mixed groups than alone (Fitzgibbon 1990). Similarly, in a large scale comparative analysis of 66 pairs of terrestrial foraging bird species worldwide, it was found that these bird species increased their feeding rate and decreased vigilance (i.e., scanning behavior) when in mixed species flocks relative to solitary or monospecific foraging flocks (Sridhar et al. 2009).

Heterospecific groups can also facilitate earlier detection of predators. Cowtail stingrays (*Pastinachus sephen*) preferred to rest with whiprays (*Himantura uarnak*) rather than other cowtail conspecifics. In these mixed species groups, whiprays responded to predators earlier than cowtails, thereby alerting cowtails to the presence of predators more effectively than in a monospecific group (Semeniuk and Dill 2006). This same effect was also inferred from studies of monkeys in the Tai rainforest in Ivory Coast. Diana monkeys (*Cercopithecus diana*) responded first to potential predators with loud alarm calls, allowing Campbell’s monkeys (*Cercopithecus campbelli*) to initiate an anti-predator response sooner than if they were among conspecifics only (Buzzard 2010). Lastly, there can be distinct reproductive benefits to polyspecific association, as animals can gain the benefits of increased group size without increasing mating competition (Buchanan-Smith 1999).

### Foraging Benefits

Where shared resources are concerned, intragroup feeding competition will nearly always occur with limited food resources. In most polyspecific associations, the anti-predator benefits of being in a group outweigh the costs of food competition, despite this competition being slightly less due to niche separation and resource switching between species (Chapman and Chapman 2000). Importantly, the ecological factors that contribute

to the formation of polyspecific groups are highly variable, and so it is difficult to generalize about competitive regimes in polyspecific associations throughout the animal kingdom. There are, however, some distinct foraging benefits to be gained by foraging in heterospecific group. Polyspecific associations have been hypothesized to increase food detection and food use. Gautier-Hion et al. (1983) found that within a community of guenons (genus *Cercopithecus*), those groups that consisted of more than one species had a more diversified diet, improved detection and defense of fruit, and exploited resources less intensely. Frugivorous primates whose home ranges differ in size but nonetheless overlap may benefit from associations by obtaining information about the location of patchily distributed fruit resources that fall outside their range. This allows these primates to locate foods that they otherwise would not access (Stensland et al. 2003). Similarly, Avila-Pires saddle-back tamarins (*Saguinus fuscicollis avilapiresi*) in the Amazon capture more insects when in association with red-capped moustached tamarins (*Saguinus mystax pileatus*), because the moustached tamarins flush the arthropod prey from the upper canopy (Peres 1992).

In a striking example of heightened resource exploitation, associations between seabirds, pelagic dolphins, and tuna serve to drive fish to the ocean surface, making them easily exploitable by the dolphins and other members of this heterospecific group (Au and Pitman 1986). In a recent experiment, Freeberg et al. (2017) tested how diversity in interspecific group composition affects foraging success in birds and demonstrated that latency was significantly shorter with increasing species composition diversity and argue that polyspecific association helps wild birds locate and exploit novel food sources more effectively.

## Social Benefits and Other Advantages

There are also distinct social, competitive, and reproductive advantages to participating in a polyspecific association. While most social interactions between heterospecifics are agonistic according to Stensland et al. (2003), immature animals in

polyspecific associations often play with immature individuals of other species, which can help develop social and motor skills for adulthood, as well as cement interspecies bonds as seen among forest monkeys (Struhsaker 1981) and oceanic dolphins (Bearzi 1996). Lastly, there can be distinct reproductive benefits to polyspecific association, as animals can gain the benefits of increased group size without increasing mating competition (Buchanan-Smith 1999).

## Conclusion

In summary, there are two major explanations as to why animals form polyspecific associations: foraging advantages and anti-predator advantages, though there are less studied social, reproductive, and competitive benefits as well. As with the evolution of social groups, the formation of polyspecific association likely has been driven by predation, as different species are able to exploit each other's vigilance, with increased foraging as a side effect of this. The cognitive implications of polyspecific association have yet to be studied, though it is accepted that mixed species groups form nonrandomly. The social cognition of mixed species groups is a matter of ongoing study.

## Ponzo Illusion

Sarah-Elizabeth Byosiore  
Department of Psychology, Hunter College,  
Thinking Dog Center, City University of  
New York, New York, NY, USA

## Synonyms

[Depth illusion](#); [Geometric illusion](#); [Linear perspective](#)

## Definition

The Ponzo illusion is a geometric visual illusion commonly presented as two horizontal parallel lines, equal in length, above one another, surrounded by a set of converging lines. These converging lines represent an intersecting feature in the display that distort the perception of the equally sized parallel lines such that the upper line (closest to the apex of the converging lines) appears to be longer in length than the lower line. In humans the Ponzo illusion has been well-studied and various theories have been used to explain susceptibility. The Ponzo illusion has also been studied in nonhuman animals (hereafter animals), with most species to date demonstrating human-like susceptibility to the illusion.

## The Ponzo Illusion

Visual illusion susceptibility occurs when visual information is unnecessarily or inappropriately adapted based on preconceptions. More specifically, geometric visual illusions are invoked when

## Polythelia

- [Supernumerary Nipple](#)

**Ponzo Illusion, Fig. 1** Three examples of the Ponzo illusion, where (a) and (c) utilize identically sized vertical lines, and (b) utilizes identically sized circles. (a) and (b) are presentations using a “converging lines” context,

whereas (c) is a presentation of a “grid inducer” context. Here, the object closer to the apex of the converging lines, or in the smaller inducer grid, appears larger than the other object. (Adapted from Byosiére et al. 2017)

the physical characteristics (e.g., size, length, color, brightness, orientation area) of a given stimulus are perceptually distorted. First discovered by the Italian psychologist, Mario Ponzo (1882–1960), the Ponzo illusion, represents a geometric visual illusion in which a size difference between identical stimuli, such as lines or shapes, is invoked due to the presence of other features presented in the display. The stimuli can be distorted by physical features in the background, foreground, or by intersecting shapes that invoke a misperception of length, size, and/or parallelism. Often, the Ponzo illusion is presented as two parallel lines, equal in length, above one another, surrounded by a set of converging lines (Fig. 1a). The parallel line presented atop, closest to the apex of the converging lines, is perceived as being longer than the line presented furthest from the apex, the lower line. Variations of the Ponzo illusion have been created using different stimuli (Fig. 1b) as well as different surrounding features (Fig. 1c). Regardless of the presentation, the theories proposed to explain the emergence of the illusion remain the same.

## Ponzo Illusion in Humans

In the human literature, the Ponzo illusion is well-studied and multiple theories have been proposed to explain susceptibility. Inappropriate size constancy scaling theory (Gregory 1963) posits that

the two identically sized stimuli are perceived to be different in size due to the placement of converging inducer lines, which induce linear perspective cues. Integration field-theory (Pressey and Epp 1992) suggests that converging inducer lines invoke attentional demands to the space in between, which results in misperception of the stimuli. More recently, tilt constancy theory (Prinzmetal and Beck 2001) proposes that perception of size depends on the interpretation of the location of the end points of the converging lines, and this interpretation of the location causes a misperception of size between the two stimuli.

Most humans demonstrate susceptibility when presented with the Ponzo illusion, and research suggests that perception of the illusion requires a high level of visual processing (Song et al. 2011). The illusion emerges after interocular transfer meaning that visual input is processed post-retinally, likely in the primary visual cortex or in higher visual areas (Song et al. 2011). Moreover, the Ponzo illusion is cognitively impenetrable, meaning that humans cannot prevent themselves from visually seeing the illusion even when aware of its presence. Interestingly, human’s visually guided actions may not be affected by the illusory-invoking properties of this illusion, as a double dissociation between vision-for-perception and vision-for-action appears to be present (Ganel et al. 2008). When asked to use an action (a grasping motion using one’s index finger and thumb) to indicate the length of the line

stimuli when presented with the Ponzo illusion, humans appear to scale the opening of their index finger and thumb to the real size of the target line and not the perceived illusory size.

It is also important to note that some variation in Ponzo illusion susceptibility has been observed within humans. Individuals living in non-Western cultures or rural areas are less likely to demonstrate susceptibility to the illusion (e.g., Segall et al. 1963). While these reasons for differences are still debated, it has led to the “carpentered-world” hypothesis. This hypothesis proposes that lines and 90° right angles are more frequently present in Western cultures; therefore, individuals exposed to this environment, especially from a young age, might be more susceptible to the Ponzo illusion (Segall et al. 1963). Interestingly, susceptibility does not appear to be solely dependent on experience. Congenitally blind children demonstrate perception of the Ponzo illusion post-cataract surgery, indicating that even within humans, the underlying mechanisms responsible for perceiving the illusion might not exclusively be learned (Gandhi et al. 2015).

The substantial literature available regarding human illusion susceptibility provides a detailed foundation which can be used to evaluate cognitive and neuropsychological mechanisms of visual processing both within humans and across other animals. As it is possible to evaluate illusion susceptibility nonverbally, this method may serve as an ideal tool to indirectly and comparatively assess perception in humans and animals (Kelley and Kelley 2014). In doing so, similarities and differences underlying psychological and cognitive processes of perception can be compared, furthering current understanding of not only human visual perception, but also animal visual perception (Kelley and Kelley 2014).

## Ponzo Illusion in Animals

To date, susceptibility to the Ponzo illusion has been evaluated across a variety of animal species (Table 1). Typically, susceptibility has been

assessed using experimental testing paradigms in which an animal is trained to make a certain choice (e.g., discrimination task, classification task, same-different task). These findings currently suggest that Ponzo illusion susceptibility in animals is rather unique. Unlike other most other geometric illusions, where inter-specific variability in illusion susceptibility has been observed (e.g., Ebbinghaus-Titchener, Delboeuf, Muller-Lyer), human-like susceptibility to the Ponzo illusion has been found in every species tested to date, except for one. Rhesus macaques (Bayne and Davis 1983; Fujita 1996, 1997), carneau pigeons (Fujita et al. 1991), horses (Timney and Keil 1996), baboons (Barbet and Fagot 2002), Sprague-Dawley rats (Nakagawa 2002), and chimpanzees (Imura et al. 2008) have all demonstrated human-like susceptibility to the illusion. On the other hand, domestic dogs have failed to demonstrate any type of susceptibility to the illusion, indicating they do not fall susceptible to the illusory-invoking properties of the display (Byosiére et al. 2017, 2018).

As the majority of species tested to date have demonstrated human-like susceptibility when presented with the illusion, it is important to note that the results observed in dogs are rather equivocal. In two studies (Byosiére et al. 2017, 2018), canine susceptibility to the Ponzo illusion was evaluated across a variety of different illusory contexts/presentations, including variations of those presented in Fig. 1. Across these presentations and using a two-choice discrimination screen-touching paradigm, dogs as a group generally demonstrated at chance performance, indicative of null susceptibility. These results suggest that unlike all other species tested to date, dogs perceptually viewed the target stimuli as being equal in size. This result appears to be consistent regardless of target stimuli used (i.e., circles or rectangles), the presentational background context (i.e., converging lines or grid inducer contexts), or the orientation in which the stimuli are embedded (i.e., vertical or horizontal). However, it is important to note that like other assessments of illusion susceptibility individual differences were observed. Certain

<sup>a</sup>Note: This publication likely represents the first to evaluate animal susceptibility to the Ponzo illusion. While the author suggests minnows experience human-like illusory perception of the Ponzo illusion, the methodology has been suggested to be obsolete and the lack of controls require further investigation before interpreting these results

subjects did demonstrate individual illusion susceptibility, some consistently so across the different variations of the illusion presented (Byosiére et al. 2017, 2018).

Regardless, six out of seven total species evaluated have demonstrated human-like susceptibility to the Ponzo illusion. Taken together, this distinctive interspecific parallel has significant implications for interpreting proposed theoretical mechanisms underlying the Ponzo illusion. As proposed by Feng, Chouinard, Howell, and Bennett (2017), such examples, in which similarities between humans and animals are observed, highlight the importance of visual illusion and perception research in animals as a comparative approach can be used to further test preexisting theories beyond what is possible in a human population (Feng et al. 2017).

Based on theories from the human literature, Ponzo illusion susceptibility is thought to be more prominent in terrestrial species compared to aerial and aquatic species as the systematic judgment of depth and distance across the horizon might invoke stronger linear perspective cues than those observed in three-dimensional space (Feng et al. 2017). As most species evaluated represent those living in terrestrial environments, this explanation may possibly explain why most animals have demonstrated perception of the Ponzo illusion. However, one aquatic (Herter 1930) and one aerial species (Fujita et al. 1991) have been tested and results suggest they are also susceptible to the illusion. Moreover, dogs, a terrestrial species, failed to demonstrate any kind of susceptibility to the illusion. Therefore, environment does not appear to predict susceptibility. Due to the limited species evaluated and the small sample sizes in these studies, it is important that additional assessments of Ponzo illusion susceptibility of animals living within aerial and aquatic environments are conducted to further investigate the relationship between environment and susceptibility.

Physiological differences in visual acuity have also been proposed to affect perception of the illusion (Table 1). The human literature suggests that Ponzo illusion susceptibility emerges as a result of depth perception and advanced visual acuity. As receding images, such as those invoked

by the Ponzo illusion, become smaller in size, retinal information can be more difficult to interpret especially for those animals which may not accurately perceive the scene visually. Thus, animals with poor visual acuity may not fall susceptible when presented with the Ponzo illusion (Feng et al. 2017). To date, the species evaluated range in visual acuity measures of 1.2 cycles/degree (rats)–65 cycles/degree (chimpanzees) (Table 1). Human visual acuity varies, but generally measures of 40 cycles/degree are generally reported (Campbell and Green 1965). Given this extreme variation in visual acuity, and the fact that most animals have demonstrated human-like susceptibility to the Ponzo illusion, it seems unlikely that animals with higher measures of visual acuity are susceptible to the illusion. Then again, many of the visual acuity measures reported stem from studies with extremely small sample sizes that may be obsolete. Therefore, caution should be used when interpreting this relationship.

## Conclusion

In conclusion, it is particularly interesting that most species, regardless of testing paradigm, environment in which they live, and/or visual acuity appear to demonstrate human-like susceptibility when presented with the Ponzo illusion. This suggests that the parallels observed may be due to other shared commonalities, bringing into question whether susceptibility is learned or innate. Practically, this question is impossible to disentangle, and likely, both play a role in the emergence of susceptibility. Regardless, the consistency observed across species suggests that the Ponzo illusion might represent an ideal geometric illusion in which to comparatively assess and develop theories of visual perception in animals.

While it can be exceptionally difficult to evaluate similarities and differences in visual perception across nonverbal animal species, the method of using illusion susceptibility to evaluate perception has been proposed to represent a unique tool in comparatively evaluating various species' perception (Kelley and Kelley 2014). This systematic

and readily generalizable approach (Kelley and Kelley 2014) allows for testing of existing theories beyond what is possible in a human population (Feng et al. 2017). In implementing this comparative framework, the Ponzo illusion is quite unique compared to other geometric visual illusions. While discrepancies in the perception of geometric visual illusions are often present both across and within animal species, most species tested to date have demonstrated human-like susceptibility when presented with the Ponzo illusion. These findings highlight the possibility that visual processing and perception of this visual geometric illusion occurs postretinally in vertebrates. The Ponzo illusion, therefore, represents an ideal illusion in which to continue conducting assessments of geometric illusion susceptibility, in which larger samples are employed, various methodological paradigms are utilized, and more species are tested to begin to further investigate this unique perceptual similarity.

## Synonyms

Area; Community; Individual; Species

## Definition

Group of individuals of same species occupying a particular area at a specific time.

## Introduction

Population refers as a group of potentially interbreeding and interacting individuals of the same species living in the same geographical place and time having common gene pool (Daniel 2007).

The various types of the population are: (a) Monospecific population: It is the population in which individuals are only one species. (b) Poly-specific population: It is referred to the population of more than one species; conversely polyspecific populations are referred to as the community.

## Population Characteristics

### Population Size

Population size is dynamic. It is referred to the total number of individual in a population

**Population, Fig. 1** Effect of natality/or birth rate and immigration as well as mortality/or death rate and emigration on the population size. Births and immigration add

individuals to a population; in other side, deaths and emigration remove individuals from a population

(Husemann et al. 2016). Population size increases by increase natality/birth rate and also immigration of individuals. Population size decreases by mortality/death rate and also emigration of individuals. Figure 1 shows that population size affects via natality and immigration as well as mortality and emigration.

### Determining the Population Size

There are three ways to determining the population size: (a) Direct counts: The most accurate way to determining the population size but seldom feasible. (b) Sample an area and then extrapolate. (c) Capture (mark) – Recapture method is used for mobile species.

### Factors Affecting Population Size

There are three factors which affect the population size. (a) Abiotic factors: sunlight and temperature, precipitation/water, soil/nutrients. (b) Biotic factors: other living organisms: prey (food), competitors, predators, parasites, disease. (c) Intrinsic factors: adaptations.

### Population Density

It represents the number of an individual per unit area/volume (Rosenberg 2011). Crude density: Density per unit total space. Ecological density: Density per unit of habitat. It is also called as economic density or specific density.

Population density can impact on the health and survival of organisms. In dense populations, pathogens can spread more rapidly (Fig. 1).

### Population Dispersion Pattern

It is the spatial pattern of individuals of a population relative to one another. There may be three types of dispersion patterns (Fig. 2) (Krebs 1928).

**(A) Uniform dispersion:** A uniform dispersion referred as individuals are evenly distributed. Uniform dispersal may be influenced by social interactions such as territoriality. **(B) Random dispersion:** In a random dispersion, the position of all individual is independent of other individuals. It occurs in the absence of strong repulsions or attractions. **(C) Clump dispersion:** Individual which are present in small localized groups or

**Population, Fig. 2** Diagrammatic representation of three types of dispersion patterns. (a) Uniform dispersion; (b) Random dispersion; (c) Clump dispersion

**Population, Fig. 3** Graphical representation of different age groups in a population. Three types of age pyramids showing in the figure which represents: (a) Pyramid with a broad base; (b) Bell-shaped pyramid; (c) Urn-shaped pyramid

patches. It may be influenced by resource availability and behavior.

**Age Structure:** Age structure of the population describes the individual of different age groups. These proportions of individuals in each age group form the age structure of that population. There are three age groups in any population that determine the reproductive status of the population (Cole 1954). These are as follow: (a) Pre-reproductive; (b) Reproductive; (c) Post-reproductive.

**Age Pyramids:** Graphical representation of different age groups in a population. Age pyramids are the best way to describe the age structure of any population. There are three types of pyramids described as follows (Fig. 3) (<http://www.environmentalpollution.in/population/population-features-of-population-explained-with-diagram/>

226). (A) **Pyramid with broad base:** population size increase (Natality is more than mortality); (B) **Bell-shaped pyramid:** population size constant (Natality and mortality approximate similar); (C) **Urn-shaped pyramid:** Population size decrease (Natality is lower than mortality).

**Life History**

The life history of any population includes some features: (a) The total number of reproductive events in the life span; (b) The total number of offspring produced during one reproductive event; (c) Parental care; (d) Generation time: It is a time period between the birth of an individual and production of its own offspring.

## Types of Life History

There are two types of the life history of population (Young 2010).

### Semelparous Type

The characteristic features of semelparous type are: (a) They have only one reproductive event in their complete life span. (b) They produce many offspring during one reproductive event. (c) Parental care is absent. (d) Generation time is very short. For example: small insect.

### Iteroparous Type

The characteristics features of iteroparous type are: (a) They have many reproductive events in their complete life span. (b) They produce very few offspring during one reproductive event. (c) Parental care is extensive. (d) Generation time is large. For example: perennial plants and human.

### Survivorship Curves

These are the plots which explain the numbers of survivors in a population at different age groups, i.e., pre-reproductive, reproductive, and post-reproductive. Three types of curves (Fig. 4) (Pearl 1944; Deevey 1947). (a) Highly concave/Type I: It represents low mortality rate until near

end. Examples: human and perennial plants. (b) Diagonal curve/Type II: Intermediate condition between type I and type II. Examples: rabbit and hydra. (c) Highly convex/Type III: It represents high mortality rate in early young life. Examples: small insects and oyster.

## Biotic Potential and Environmental Resistance

**Biotic potential:** This is the maximum rate at which the populations of a given species can increase when there are no existences of limiting factors. **Environmental resistance:** This is sum total of all environment limiting factors that act together to limit the biotic potential of a population from being attained (Odum 1971).

**Note:** Together, biotic potential and environmental resistance decide the carrying capacity (K) of any population.

### Carrying Capacity (K)

It is maximum numbers of individuals of a population which may accommodate by the environment. It fluctuates with environments. Carrying capacity (K) can be different for two different

### Population,

**Fig. 4** Graphical representation of survivorship curves in a population at different age groups

populations of the same species in two different areas because of availability of resources such as food, water, and space.

## Population Dynamics/Population Growth Models

Every population has a characteristic pattern of its growth, i.e., growth form of the population. Such growth forms characterize the interaction of biotic potential and environmental resistance.

There are two types of growth models shown by a population (Snider and Brimlow 2013).

### Exponential Growth Model

It explains the growth of population in ideal condition (no growth limitation and no competition) (Fig. 5a).

The formula of growth model:  $\frac{\Delta N}{\Delta t} = r_{\max} N$

Here,  $N$  = population size;  $t$  = time;  $r$  = growth rate (species-specific)

$\frac{\Delta N}{\Delta t}$  = change in the size of a population

### Logistic Growth Model

It explains the growth of population in real condition (extreme environment and resource limitation) (Fig. 5b).

The formula of growth model:  $\frac{\Delta N}{\Delta t} = rN\left(\frac{K-N}{K}\right)$

Here,  $N$  = population size;  $t$  = time;  $r$  = growth rate (species-specific)

$\frac{\Delta N}{\Delta t}$  = change in the size of a population

$K$  = carrying capacity

## Population Ecology and Evolution: (r/K Selection Theory)

The two evolutionary “strategies” are termed r-selection, for those species that generate many “cheap” offspring and live in unsteady environments and K-selection for those species that generate few “expensive” offspring and live in steady environments (Table 1). The terminology of r/K-selection was given by the ecologists Robert MacArthur and E. O. Wilson in 1970 (Pianka 1970).

## Population Interactions

In an ecosystem, each species of the different population are connected to each other directly or indirectly. These interactions may be beneficial

**Population, Fig. 5** Population growth models: (a) Exponential growth model; (b) Logistic growth model

**Population, Table 1** Comparative study of r- and K-selection

| r- selection                                                                            | K- selection                                                          |
|-----------------------------------------------------------------------------------------|-----------------------------------------------------------------------|

| Competition         | —         | —         |

**Note:** ‘+’ sign for beneficial; ‘—’ sign for harmful (detrimental); ‘0’ sign for neutral

or harmful (National Council of Educational Research and Training 2018). Table 2 shows the various types of interactions present between species of the population.

**Sociobiology/Social Behavior**

Two or more than two individuals of population perform a work together. These are: (a) Agnostic behavior: Agonistic behavior is any Sociobiology related to fighting. The term has a broader meaning than aggressive behavior because it includes threats, retreats, displays, conciliation, and placation. The term was given by Scott and Frederickson in 1951 (Edward 2001). It is performed by an individual of the same species or different species when they compete for common resources. (b) Courtship behavior: It is also called mating behavior. Courtship behavior is the social behavior by which different species are selecting their partners for reproduction. (c) Altruistic behavior: It is a type of social behavior in which the individual who perform altruistic act save the life of other individuals of the population at the risk of its own life (Graham 2008).

## Positive Reinforcement

Roberto Barata  
Ethology Institute, Int, Cambridge, UK

## Synonyms

[Instrumental learning](#); [Learning](#); [Operant conditioning](#); [Reinforcement](#)

## Definition

Positive reinforcement is an operant procedure in which the addition of a stimulus increases an aspect of a particular behavior. “A positive reinforcer is

everything that increases the frequency, intensity or duration of a certain behavior when presented either simultaneously or immediately after that behavior takes place.” (Abrantes 2013, p. 12).

## Introduction

Positive reinforcement it is a widely accepted and used term especially in animal training, because of the pleasant connotations it creates. Skinner’s behavioral model analysis shows more efficiency of using several reinforcement models in behavior modification of humans and nohumans species (Skinner, 1966, 1969, 1986).

‘Positive’ does not describe the nature of the consequence; it indicates the addition of a stimulus. ‘Reinforcement’ indicates a strengthening of an aspect of the behavior.

In operant conditioning, reinforcers (and punishers) must have the right quality and intensity to work. Abrantes (2013) mentions their ‘window of opportunity.’ Reinforcers depend on some state of deprivation. For example, food may work as a reinforcer if the individual is hungry and water if it is thirsty. Therefore, the quality of the reinforcer is essential for it to function as envisaged. The intensity of the reinforcer is also fundamental. Too low an intensity does not affect the behavior, and a too high one creates another behavior.

## Positive Reinforcement Versus Rewards

Positive reinforcement is sometimes called rewarding or reward learning. Skinner has rejected this term: “The strengthening effect is missed when reinforcers are called rewards, [...] people are rewarded, but behavior is reinforced” (1986, p. 569).

Although we find the term “reward learning” in the learning, biology and neuroscience literature, the events labeled as rewards often fail to increase or strengthen the following behavior. A stimulus may reinforce a particular behavior in one specific situation but not in another (Sy et al. 2010); “[...] a reinforcer can by definition do nothing but increase an aspect of a behavior (Abrantes 2013, p. 20).

## Positive Reinforcement Versus Negative Reinforcement

Negative reinforcement strengthens a behavior by the removal of a stimulus or a decrease in its intensity.

Both positive and negative reinforcement increase the frequency, intensity or duration of a behavior. The difference is that while positive reinforcement adds, negative reinforcement removes something.

Identifying consequences that strengthen behaviors is a useful strategy for behavior modification but is not always easy to identify whether it is a positive or a negative reinforcer that is working in a particular situation. Iwata (1987, 2006) gives the example of a person in a cold room who turns up the heat. Is the reinforcer an increase (positive reinforcer) or a decrease (negative reinforcer) in the temperature?

## Practical Applications of Positive Reinforcement

Behavior modification depends on several conditions. Both reinforcers and punishers ('inhibitors' according to Abrantes, 2–13, p. 16) are always subject to the individual, the behavior and the occasion.

Some learning procedures to change or strengthen behaviors, e.g., shaping, chaining and differential reinforcement apply positive reinforcers.

Behavioral therapies apply these techniques to both human and non-human behavior, and to behavior management in various environments and situations.

## Reinforcement and Motivation

Mcfarland (2006), defines motivation as “[...] A reversible aspect of the animal's state that plays a causal role in behaviour. Changes in behaviour in an unchanging environment may be due to irreversible processes such as learning, maturation, or injury, or reversible motivational processes. [...] An animal's motivational state changes continually as a result of both external

and internal changes. [...] The dominant motivational tendency is the one that controls the ongoing behaviour. The dominant tendency inhibits the tendencies for other aspects of behaviour.”

Hull (1952) believes that humans and non-humans act because of motivational states called drives, caused by a period of deprivation (such as food). His drive-reduction theory attributes the effectiveness of a reinforcer to the reduction of the drive. It works mainly with primary reinforcers because they alter a physiological state of the individual.

Other motivation theories appear to confirm the efficiency of working with motivational processes though under the constraint of conditions and correct application.

affiliation

## Definition

Affiliative behaviors between previous opponents, or between either aggressor or victim and a third-party individual, after an agonistic interaction.

## Introduction

We have all experienced it: two of your colleagues are having an argument over the order of authorship on an impactful new paper, and now your group is in shambles. They fight and scramble to

the detriment of all group members. However, not long thereafter one of the two reaches out to the other; their friendship is restored, perhaps even with an embrace or a handshake, and normalcy, as well as productivity, returns to the group. This form of relationship-mending behavior is not exclusive to humans – not even to primates – but can be found in many species of animals. In fact, conflicts within social groups are common, as individuals benefit from protecting or accessing resources that are threatened or held by others. An individual might behave aggressively over access to food, mates, or social status, as this can benefit fitness. However, aggression also leads to elevated levels of anxiety and distress in both the aggressor and victim (Kutsukake and Castles 2004) and can cause injury. If further aggression is not diminished, it risks destabilizing group dynamics (Katsu et al. 2018). Conflict reduces cooperation and the overall benefit of group living (Aureli et al. 2002; de Waal and Yoshihara 1983). To prevent loss of relationship benefits, several behavioral mechanisms have evolved that mend damage sustained from conflicts (Aureli and de Waal 2000). One such mechanism is post-conflict affiliation. Post-conflict affiliation refers to affiliative behaviors between two previous opponents (reconciliation; Arnold et al. 2010) or between either victims or aggressors and a third party (third-party affiliation; Romero et al. 2011). Post-conflict affiliative behaviors follow at least two criteria: (i) they are exhibited more after an agonistic interaction than when no conflict has happened, and (ii) they have a positive effect on the relationship between previous opponents and/or reduce anxiety levels. Additionally they often involve close proximity and bodily contact (de Waal and van Roosmalen 1979).

Post-conflict affiliation was first observed in chimpanzees (*Pan troglodytes*; de Waal and van Roosmalen 1979) and has since been found in many other primate species (see Aureli et al. 2002 for a review). Similar mechanisms have also been described in, for example, spotted hyenas (*Crocuta crocuta*), domestic goats (*Capra hircus*), wolves (*Canis lupus*), and bottlenose dolphins (*Tursiops truncatus*), as well as in birds such as the common raven (*Corvus*

*corax*) and budgerigars (*Melopsittacus undulatus*) (Cordoni and Palagi 2008; Fraser and Bugnyar 2010, 2011; Lazzaroni et al. 2017; Schino 1998; Wahaj et al. 2002; Weaver 2003; Yamamoto et al. 2020). Interspecific post-conflict reconciliation has also been reported to occur between cleaner fish and their hosts (*Labroides dimidiatus*; Bshary and Würth 2001).
